It was pointed out many years ago that quadrature images result from inaccurate 90° phase shifts or unequal quadrature channel amplitudes, and that these faults can be remedied by a phase cycle known as CYCLOPS which involves simultaneously cycling the pulse sequence and receiver through the sequence $x, y, -x, -y$.²³ In NOESY, it is only necessary to cycle the last pulse and receiver. When this cycle is combined with the cycles for removal of other artifacts, it produces the 16-step cycle indicated in Table 1. Note that the cycle is designed so that the artifacts likely to be most troublesome, single quantum coherence and axial peaks, are removed by adjacent steps. It will be seen that this phase cycle does nothing to reduce F_1 quadrature images. If these images are troublesome, they are most simply reduced by careful adjustments of the phase shifts of the receiver (if possible) and the amplitudes of the two channels.

Table 1 Phase Cycle for the Suppression of Artifacts in NOESY

Step ^a	90°	90°	90°	Acquisition
1	x	x	x	x
2	$-x$	x	$-x$	x
3	y	y	x	x
4	$-y$	y	$-x$	x
5	x	x	y	y
6	$-x$	x	$-y$	y
7	y	y	y	y
8	$-y$	y	$-y$	y
9	x	x	$-x$	$-x$
10	$-x$	x	x	$-x$
11	y	y	$-x$	$-x$
12	$-y$	y	x	$-x$
13	x	x	$-y$	$-y$
14	$-x$	x	y	$-y$
15	y	y	$-y$	$-y$
16	$-y$	y	y	$-y$

^aSteps 1 to 2, 3 to 4, etc. remove axial peaks resulting from longitudinal relaxation during τ_m and magnetization that is transverse during τ_m . Steps 1 to 3, 2 to 4, etc. remove magnetization that is double quantum during τ_m . Steps 1, 5, 9, 11, etc. remove quadrature images in t_2 .

Use of a 16-step phase cycle implies that the number of scans per t_1 increment (or for each of a pair of t_1 increments, if a complex quadrature detection is used in t_1) must be a multiple of 16. However, because the most essential elements of this phase cycle are contained in the first group of four steps, use of a phase cycle that is a multiple of four rather than 16 steps will only lead to increased F_2 quadrature images, and will not hinder the workings of the rest of the phase cycle.

3.1.5 Residual Solvent

Many NOESY spectra of biological molecules are run in H_2O (containing a small quantity of D_2O for the field/frequency lock). Because this signal is so intense, it causes a range of problems in NOESY spectra. This topic is discussed more generally elsewhere (see *Water Signal Suppression in NMR of Biomolecules*), but a few words are appropriate here.

The most obvious problem is that to digitize such an intense signal, the receiver gain must be turned down so low that the signal from the sample is not adequately digitized. Many spectrometers now incorporate 16-bit digitizers which reduce the problem, but some method of reducing the solvent signal entering the receiver is necessary. This is done either by presaturation of the solvent or by the use of a composite pulse sequence prior to detection, often assisted by field gradients.

In many cases, the carrier frequency is set to coincide with the solvent signal. This allows solvent saturation/pulsing to be coherent with the other pulses, which improves solvent suppression markedly.²⁴

The residual solvent signal tends to cause baseplane problems in NOESY. In particular, there are stripes parallel to the F_2 axis tailing out from the solvent signal. Many methods have been proposed to deal with this, but a combination of spin echo acquisition and time domain filtering appears to offer the best solution.²⁵

3.2 The Setting of Experimental Parameters

Most experimental parameters for NOESY are very easy to set. All pulse widths should be 90° . The delay τ_m has been discussed above and the choice of a suitable value depends on whether sensitivity or precise distance information is preferred. The delay t_D should be long enough that most signals have relaxed close to equilibrium: in practice a value of at least 0.7 s is often adequate for macromolecules.

The number of points in t_2 is limited only by disk space and the required resolution: with present data storage devices, 4k complex points is not unreasonably large. With larger molecules, the signal may well have decayed to zero long before this, in which case fewer points are necessary. By contrast, it is not generally feasible to collect so many points in t_1 , and this value is always a compromise between sensitivity and time pressure (which require fewer points) and resolution (which requires more points). Again, with larger molecules, the signal decays more rapidly and fewer t_1 points will be used. Typically 300–512 complex points are acquired. If too few t_1 points are acquired, the interferogram will be severely truncated (i.e. it will be cut off before it has decayed to zero). Fourier transformation of truncated FIDs produces 'sinc wiggles' around each peak [Figure 5(a)], which can be reduced but not eliminated by a suitable window function (see *Data Processing*). Such wiggles are particularly evident in 2D spectra around the diagonal peak of sharp intense resonances such as methyl groups, which have signals that decay slowly in t_1 [Figure 5(b)].

The increments in both dimensions depend on the spectral widths and also on whether complex or real data are being acquired, as indicated in equations (9) and (10). In t_1 , there is no point in acquiring over a spectral width wider than that defined by the signals of the sample. Greater resolution is

Figure 5 The effect of truncation is to give sinc wiggles. (a) Sinc wiggles in 1D. (b) Sinc wiggles in the F_1 dimension resulting from truncation in t_1

obtained by using a spectral width smaller than the entire range, but unless selective pulses are used this strategy runs the risk of severe complications from the folding in of signals from outside the spectral width, since no filter is applied to such signals. In t_2 , there may be a benefit in 'oversampling' (using a spectral width wider than that of the sample) to achieve a flatter baseplane,^{25,26} and it is in any case advisable to use a spectral width at least 5% larger than the width of the signals to avoid distortion of the extreme signals by the audio filter.

3.3 Data Processing

This topic is discussed more generally elsewhere (see *Data Processing*). In NOESY, data processing is simple and consists largely of finding the best filters for the data, phasing the spectrum, and flattening the baseplane. The data are not greatly sensitive to the filters used and sine-bell or sine-squared-bell filters are often suitable. Phasing is independent in the two dimensions.²⁷ Normally, phasing in t_2 can be determined by phasing the first FID of the 2D file, while the appropriate phase in t_1 can be worked out from the initial delay between the first two pulses.

4 APPLICATIONS OF NOESY

4.1 When Should NOESY be Used?

The NOE is the most widely used structural parameter in organic and biological NMR. Although many experiments have been proposed for measuring NOEs, only three are commonly used: one-dimensional pseudo-steady-state NOE difference, NOESY, and the rotating frame NOE experiment known as ROESY or CAMELSPIN.²⁸ The choice of which experiment to use is essentially dictated by the size and correlation time of the molecule.

In small molecules, cross relaxation is slow. NOEs therefore build up slowly and external relaxation competes favorably with the NOE. NOEs are therefore often small. NOESY is therefore often very insensitive and takes a long time because of the long relaxation delays required [e.g. Figure 3(b)]. By comparison, 1D methods are usually more sensitive because the NOE can be driven to a steady state. In addition, in

small molecules there is usually no difficulty in achieving the specific irradiation required because there are fewer signals present. It is therefore generally preferable to use 1D difference methods. However, in cases where there are many irradiation targets, it can be more time-efficient to use NOESY or ROESY experiments.

As the size of the molecule under investigation increases, and therefore the correlation time τ_c of the molecule increases, the maximum homonuclear NOE goes from +50% to -100%, going through zero at $\omega_0\tau_c = 1.12$. As the NOE approaches zero, both the 1D NOE and the NOESY experiments become insensitive. However, cross relaxation in the rotating frame is still very significant and so ROEs can still be observed. This is therefore the only experiment useful in the region around $\omega_0\tau_c = 1.12$.

Above this point, NOESY is usually more sensitive, easier to set up, and produces fewer artifacts, and is therefore generally preferred over ROESY. However, the problem of spin diffusion is less severe in ROESY than in NOESY. This is because in ROESY, as in all cases where $\omega_0\tau_c < 1.12$, a relayed or spin diffusion NOE has the opposite sign to a direct NOE and therefore can be easily distinguished. There are therefore good reasons for using ROESY even for very large molecules. Further discussion of these points may be found elsewhere (see *Nuclear Overhauser Effect and ROESY*).

4.2 Studies of Macromolecules

NOESY is the most widely used technique for measuring NOEs in large molecules such as proteins and nucleic acids. It is used for spectral assignment (e.g. sequential assignment) and for obtaining structural parameters. Many examples may be found elsewhere (see *Biological Macromolecules: Structure Determination in Solution; Carbohydrates and Glycoconjugates; Nucleic Acid Structures in Solution: Sequence Dependence; Structures of Larger Proteins, Protein-Ligand, and Protein-DNA Complexes by Multi-Dimensional Heteronuclear NMR*). NOESY is an excellent tool for obtaining qualitative information about internuclear distance, but is less good at providing quantitative information. In part, this is because the most reliable quantitative information is obtained at very short mixing times where the sensitivity is lowest and artifacts are most prominent, and also because it is not easy to integrate the volume of NOESY cross peaks accurately, particularly in crowded spectra. However, for the most part, the limitations are inherent in the systems under study. NOEs can only be interpreted quantitatively when the dynamics of the system are well characterized, and in almost all cases not enough is known about the internal dynamics of macromolecules in solution to allow the full precision of the data to be used. Nevertheless, many studies have shown that the number of structural constraints is more critical than their precision. Recently, stereospecific assignments in proteins have allowed a large increase in the number of NOE constraints, and thereby provided much better definition in the structures calculated from them. There is currently much new development in the use of heteronuclear relaxation parameters to characterize molecular dynamics, and it may be that this information can be combined with information from NOEs to allow more precise NOE constraints to be used.

5 VARIATIONS ON THE NOESY EXPERIMENT

Many variations of NOESY experiments have been proposed. Some of these are aimed at achieving flatter baseplanes, better solvent suppression, smaller diagonals, etc., and some are new pulse sequences designed to prize out more structural information from intractable data. Of these, the most useful are the three- and four-dimensional experiments described elsewhere in this Encyclopedia, which add on extra pulses and delays to separate a crowded two-dimensional spectrum into a series of subspectra.²⁹ Alternatively, simplification can be provided by the use of selective pulses, also described elsewhere. Crowded spectra can be made tractable by 'relaying' cross peaks to empty regions of the spectrum, which is done by combining the NOESY pulse sequence with a double quantum, TOCSY, or COSY experiment.

A variety of heteronuclear NOESY experiments, involving saturation of protons and observation of the heteronucleus, have been proposed. The only generally useful application of heteronuclear NOEs is as a method of signal enhancement, for example in broadband decoupled ¹³C NMR. Observation of specific heteronuclear NOEs has found little application. Heteronuclear 2D NOE experiments³⁰ in particular are of limited application, partly because they are not an efficient way of observing NOEs, and partly because the heteronuclear NOE is inherently small in almost all the cases where a two-dimensional experiment would be of most applicability, i.e. for large molecules. For example, the maximum NOE to ¹³C from irradiation of ¹H in a slowly tumbling molecule is only 15%.

There are a few NOESY variations that are designed to provide additional information to the normal experiment. For example, use of the pulse sequence $90^\circ, t_1, 90^\circ, kt_1, 90^\circ$ (with k in the range 10–100), the so-called Accordion experiment, generates a dataset in which the t_1 decay envelopes depend on processes occurring in both t_1 and τ_m .³¹ The lineshapes in F_1 therefore contain information on the rates of exchange processes occurring during the mixing period, which can be obtained by curve fitting or reverse Fourier transformation. The experiment can be suited to the range of exchange rates by an appropriate choice of k . This method is only applicable to relatively simple spectra, because of the difficulty of fitting overlapped lineshapes.

1 INTRODUCTION

One of the key goals of materials science is the establishment of structure–property relationships in order to improve known and design new materials. This holds in particular for synthetic polymers, whose properties depend on both the molecular structure and the organization of the macromolecules in the solid state: their phase structure, morphology, molecular order and molecular dynamics.^{1,2} Macroscopic as well as microscopic parameters are influenced by processing that follows the chemical synthesis. This calls for powerful analytical tools that can probe these aspects in the material as it is used, predominantly in the solid state. The structural aspects are studied mostly by scattering techniques or by microscopy. Information about dynamic aspects are deduced mainly from scattering or relaxation experiments.³ Among these, nuclear magnetic resonance^{4,5} is well established in structural characterization of liquids or compounds in solution; however, this is much less the case for solids.^{6,7} Moreover, NMR offers numerous ways to study dynamic aspects over a large range of characteristic rates. The main advantage of NMR is its unprecedented selectivity. Thus, it is desirable to exploit this technique for studying the structure and dynamics of solid polymers.^{7,8} However, owing to the presence of angular-dependent anisotropic interactions, the spectral resolution of solid state NMR spectra is orders of magnitude lower than that of high-resolution NMR in liquids. Important improvements were achieved in the 1970s by combining high-speed mechanical rotation of the sample with ingenious manipulations of the nuclear spins, such as multiple pulse irradiation, high-power decoupling and cross polarization.⁹ Moreover, two- and higher-dimensional NMR techniques have been introduced that offer fundamental advantages.¹⁰ First, as in liquids, the introduction of a new frequency dimension provides a means to increase the spectral resolution. Even more importantly, multidimensional spectroscopy also provides routes to new information, unavailable from 1D spectra even in the limit of high resolution. Experiments can be designed that correlate different spin interactions providing

different structural information, or relate various states taken up by the molecular unit during different time periods by exchange, and in this way they can probe dynamic processes in real time.

Progress in multidimensional solid state NMR has been hampered by experimental and conceptual difficulties, which have now been overcome.^{11–14} This article briefly outlines some of the main concepts and illustrates the information available from multidimensional solid state NMR spectra about polymer structure and dynamics through selected experimental examples, mainly from the author's laboratory.

Polymer dynamics is of central interest in our studies. Of the great variety of molecular motions possible in polymers (e.g., translations, rotations, and vibrations), rotations have the most pronounced effects on NMR lineshapes and relaxation parameters. Thus, multidimensional NMR provides, in particular, unique information about rotational motions. Their timescales are followed in real time over many orders of magnitude, covering in particular the regime of slow motions, which govern the mechanical properties of polymers. Moreover, the higher-order correlation functions provided by multidimensional NMR yield previously inaccessible model-independent information about the geometry of rotational motions, the orientational memory of molecular units involved in complex dynamics, and the nature of nonexponential relaxation in disordered systems. This information collected for a variety of polymers should eventually lead to a better understanding of their mechanical and rheological behavior, which is of interest not only for conventional but also for new advanced polymeric materials.

Two other aspects are particularly important for establishing structure–property relationships for polymer materials, namely, chain alignment in partially ordered systems and domain sizes in heterogeneous polymer materials. The orientation of macromolecular units is used to improve the properties of polymers for such different applications as high-tensile-strength fibres and nonlinear optical materials for information technology. Advanced polymer materials almost inevitably consist of more than one component, which often leads to phase separation. Careful design of the molar ratios as well as the size, composition, and morphology of the different phases offers a means to control the mechanical, electrical, and optical properties. Small domains that extend over only a few nanometers, as well as interfacial regions between the different phases, are particularly difficult to characterize. Major advances have been achieved in these areas by introducing the concepts of multidimensional spectroscopy. The new solid state NMR techniques nicely supplement well-established scattering and microscopic methods, as demonstrated by various experimental examples and by explicit comparison.

2 SOLID STATE NMR

The various aspects of solid state NMR are treated in detail in other articles in this Encyclopedia. Therefore, only a brief outline of the techniques used in the applications described below are given here. A full treatment is also available in our extended monograph on solid state NMR and polymers.¹⁴

2.1 One-Dimensional NMR

Solid state NMR exploits anisotropic, angular-dependent interactions of nuclear spins with their surroundings,^{4,5} in particular magnetic dipole–dipole coupling of nuclei among themselves. This leads to broad NMR lines covering approximately 50 kHz for ^1H – ^1H homonuclear coupling and approximately 25 kHz for ^1H – ^{13}C heteronuclear coupling. The anisotropy of the chemical shift results in powder patterns covering approximately 15 kHz at a field strength of 7 T. In addition to these magnetic interactions, nuclei with spin $I > \frac{1}{2}$ can also have electric quadrupole moments and are subject to quadrupole coupling to the electric field gradient at the nuclear site. For ^2H ($I = 1$) in C– ^2H bonds, it leads to spectral splittings of about 250 kHz. Since C–H bonds are common in polymers, ^2H labeling is particularly useful.

If one of the above mentioned couplings dominates, either because of its strength or because the others have been suppressed by decoupling, the angular dependence of the NMR frequency in high magnetic fields is alike for all couplings, and is given by

$$\omega = \omega_L + \frac{1}{2}\Delta(3\cos^2\theta - 1 - \eta\sin^2\theta\cos 2\phi) \quad (1)$$

Here ω_L is the Larmor frequency, Δ describes the strength of the anisotropic coupling (i.e., the anisotropic chemical shift or ^{13}C – ^1H dipole–dipole coupling for ^{13}C or the quadrupole coupling for ^2H), and η is the asymmetry parameter describing the deviation of the anisotropic coupling from axial symmetry ($0 \leq \eta \leq 1$). The angles θ and ϕ are the polar angles of the magnetic field $\mathbf{B}_0$ in the principal axis system of the coupling tensor. This in turn is often simply related to the molecular geometry, with the unique axis lying along a bond direction (e.g., for dipole–dipole coupling along the ^{13}C – ^1H bond, and for quadrupole coupling along the C– ^2H bond), or perpendicular to an sp^2 plane as for ^{13}C chemical shift tensors in aromatic rings, etc. Depending on the total spin involved, signals described by equation (1) and their mirror images with respect to ω_L may be superimposed, and in powder samples spectra for all orientations are added to yield the powder lineshape (e.g., the Pake pattern for ^2H with spin $I = 1$).

These anisotropic interactions can be removed under rapid magic angle spinning (MAS), yielding liquid-like spectra if the spinning frequency ω_R is significantly larger than the width of the anisotropic powder pattern ($\omega_R \gg \Delta$). In the slow-spinning regime, $\omega_R < \Delta$, the centerband in the isotropic chemical shift is flanked by sidebands at multiples of ω_R , thus retaining information about the anisotropic coupling.

A few examples of 1D NMR spectra are collected in Figure 1, displaying single ^{13}C lines at the isotropic chemical shifts [Figure 1(a)], a chemical shift powder pattern for ^{13}C in a carboxyl group and its relation to the molecular geometry [Figure 1(b)], a ^{13}C MAS sideband pattern [Figure 1(c)], and ^2H NMR lineshapes for an isotropic powder [Pake pattern, Figure 1(d)], a uniaxially drawn fiber [Figure 1(e)], and a phenyl ring with motional averaging due to flipping about the axis shown [Figure 1(f)].

2.2 Two-Dimensional NMR

A 2D NMR spectrum is generated by recording a two-dimensional data set following pulsed irradiation as a function

Figure 1 Examples of solid state NMR spectra: (a) ^{13}C CP MAS spectrum displaying isotropic chemical shifts of different functional groups; (b) ^{13}C powder pattern for carboxyl group, governed by chemical shift anisotropy and relationship of the principal axes system of the shielding tensor to the molecular framework; (c) ^{13}C sidebands due to anisotropic chemical shift and slow MAS; (d) ^2H NMR lineshape for rigid isotropic powder (Pake pattern); (e) ^2H NMR lineshape for a uniaxial fiber; (f) ^2H NMR lineshape for flipping phenyl rings

of two time variables, as shown schematically in Figure 2(a), and subsequent double Fourier transformation. The development of the nuclear spin system in the evolution period with incremented time t_1 at the beginning of the pulse sequence provides the basis for the first frequency dimension ω_1 . The NMR signal is detected in the detection period with time t_2 at the end of the pulse sequence, providing the basis for the second frequency dimension ω_2 . In the exchange experiments described here, a variable mixing period of duration t_m , during which dynamic processes can take place, is inserted between evolution and detection. In this way, slow molecular dynamics are probed in real time. The concept of 2D spectroscopy is readily extended to three and higher dimensions by inserting additional evolution and mixing times.

The most important aspects of 2D NMR are exemplified in Figure 2(b)–(d). First, 2D NMR is often used to increase the spectral resolution of solid state NMR spectra by separating different interactions. As an example, consider 1D sideband patterns. These are often hampered by a severe loss of spectral resolution due to overlapping sidebands of ^{13}C with different isotropic chemical shifts. This loss of resolution is circumvented at the expense of a new frequency dimension, as demonstrated in Figure 2(b), where the sideband patterns for the different sites experiencing different isotropic chemical shifts are separated from each other.

Other 2D NMR techniques aim at obtaining new information by correlating different interactions. As a specific example, Figure 2(c) displays a 2D NMR spectrum correlating a ^{13}C chemical shift with a ^{13}C – ^1H dipolar powder

Figure 2 Principles of 2D NMR spectroscopy: (a) basic pulse sequence; (b) separation of isotropic and anisotropic chemical shifts; (c) correlation of anisotropic chemical shift and dipolar interaction; (d) 2D exchange spectrum reflecting the reorientation about the angle β through an elliptical exchange ridge

pattern. Since the dipole–dipole coupling is well understood in terms of bond lengths and angles, such spectra provide valuable information about the orientation of the principal axes of the chemical shift tensor in relation to structural units such as CH_2 – groups etc.

As far as applications to polymers are concerned, 2D exchange NMR has proved to be particularly valuable. First of all, by varying the mixing time t_m , slow dynamic processes in the range of milliseconds to seconds can be followed in real time. Moreover, 2D exchange NMR spectra yield unique and model-independent information about the geometry of rotational motions. In fact, for axially symmetric tensors, ubiquitous in ^2H NMR of polymers, the 2D exchange spectrum yields elliptical ridge patterns from which the angle about which the molecules have rotated can be read off with a ruler [Figure 2(d)].

2.3 Multidimensional NMR

The concepts of 2D NMR are readily extended to higher dimensions. By combining the different schemes of 2D NMR, a large variety of three-dimensional experiments can be designed, as discussed, for example, for liquid state NMR by Griesinger et al.¹⁵ In liquid state NMR, 3D techniques are mainly used to increase the spectral resolution. Although this is also an important aspect in solid state NMR (see below), 3D exchange NMR as shown schematically in Figure 3 offers fundamentally new information about higher-order correlation functions of complex motions in the solid state. Since the orientation of a given molecule is probed three times, different pathways taken by the molecule from the beginning to the end lead to different exchange signals. Thus, different motional mechanisms may be distinguished. Such information is inaccessible from 2D NMR, where the orientation of the molecule is measured only twice, and therefore no information is available about the trajectory a molecule follows when rotating from one orientation to another. Specific examples of applying three- and higher-dimensional NMR techniques to polymers are discussed below.

Figure 3 Principle of 3D exchange NMR: (a) pulse sequence; (b) corresponding spectral cube

2.4 Spin Diffusion

Solid state NMR can also provide information about intermolecular distances and domain sizes in heterogeneous polymers by means of spin diffusion, i.e., the diffusion of nuclear magnetization through the sample without transport of material. It is mediated by dipolar couplings, and therefore is most efficient among protons.⁴ Figure 4 demonstrates schematically the connection between the spatial distribution of proton magnetization within the sample and the solid state NMR spectra for a two-phase system with spatially constant proton density. In equilibrium, the proton polarization is spatially constant, and the relative signal intensities in an NMR spectrum reflect the integral chemical composition of the sample. Differences in the chemical structure or in local molecular mobility can be used to select the proton magnetization in one component (A) and suppress it in the other (B) [Figure 4(a)]. The subsequent redistribution of magnetization by ^1H spin diffusion is monitored by NMR spectroscopy [Figure 4(b)]. For short times, the mean-square distance $\langle x^2 \rangle$ that the magnetization moves within time t is given by $\langle x^2 \rangle = aDt$, where D is the spin diffusion constant of the system under study. The factor a depends on the geometry of the packing (e.g., lamellar, cylindrical, or spherical). The spin diffusion constant D is related to the strength of the dipolar coupling as reflected in the width of the ^1H NMR

Figure 4 Schematic representation of ^1H spin diffusion in a two-phase system (A,B) with spatially constant proton density: (a) spatial distribution of ^1H magnetization; (b) NMR spectra for different mixing times t_m

spectrum, and has been calibrated for polymers of different molecular mobility by comparing spin diffusion data with direct measurements of domain sizes by X-ray scattering and electron microscopy.^{16,17}

3 APPLICATIONS

3.1 Conformational Structure

The packing behavior of polymers depends strongly on their chain microstructure.¹⁸ In particular, it is well known that only stereoregular macromolecules can crystallize. A schematic representation of the carbon backbone of an amorphous polymer is depicted in Figure 5(a). In order to specify the conformation of such a segment, one must know the bond length l , the valence angle Θ and the rotational angles Φ_i . The rotational potential $E(\Phi_i)$ around the central C–C bond in *n*-butane is plotted in Figure 5(b). The minima for the *gauche* conformers are higher than that of the *trans* by about 3.5 kJ mol⁻¹. Since this energy difference is comparable to the thermal energy at ambient temperatures, a large number of

conformations is normally present in an amorphous polymer. Therefore, experimental techniques are needed that can check the conformational statistics.

NMR of polymers in solution is well established for determining the chain microstructure.^{6,19} Glassy solid state amorphous polymers typically display broad ¹³C cross polarization magic angle spinning (CP MAS) NMR lines due to an inhomogeneous superposition of contributions from different conformations. These conformational effects on ¹³C chemical shift have traditionally been attributed to the shielding of a reference carbon C⁰ by the γ -substituent C γ [see Figure 5(b)] in a semiempirical fashion ('the γ -*gauche* effect').^{6,8,19} It has been shown that these shifts can be calculated quantitatively on the ab initio level²⁰ by exploiting the high computing power of modern workstations and advanced schemes for calculating NMR chemical shifts, such as *individual gauge for localized orbitals* (IGLO).²¹ Thus, it is hoped that eventually the spread in chemical ¹³C shifts in amorphous polymers can be analyzed to provide structural information, in particular because profound correlations of the chemical shift with specific geometrical aspects such as C–C bond lengths and dihedral angles emerge.

As a specific example, Figure 6(a) displays the ¹³C CP MAS spectrum of atactic polypropylene (aPP), with the assignment of the two partially resolved peaks and the shoulder corresponding to specific conformations of a tetrameric unit depicted in Figure 6(b). The assignment is readily made by comparison with the chemically shifted peak positions of the solid state ¹³C NMR spectra of crystalline isotactic²² and syndiotactic polypropylene.²³ In the glassy state, the peaks are broadened owing to differences in the geometry²⁰ and to the fact that numerous configurations contribute to the three main conformations, as discussed in detail elsewhere.²⁴

(b) The potential energy E for rotation about the central carbon of a butane unit in a polymer chain together with Newman projections illustrating the different interactions between the atom C⁰ and its γ -*gauche* substituent C γ for the conformations *gauche*– (g–), *trans* (t) and *gauche*+ (g+)

3.2 Molecular Order

Structural characterization of polymers often requires the determination of the alignment of macromolecular chains.²⁵ Orientation in polymers is often induced by the production process, and has strong effects on product properties. Through the angular-dependent NMR interactions, orientation is amenable to NMR experiments. As opposed to most classical techniques, the order of both crystalline and amorphous components can be studied. For ²H- or ¹³C-enriched samples, one-dimensional experiments are sufficient to obtain orientation distributions in terms of a single angle.²⁶ In order to reconstruct two-dimensional orientation distributions, or to resolve overlapping patterns in natural abundance ¹³C spectra, multidimensional spectra are required. Two examples are discussed here. Both involve 3D spectra of ¹³C in natural abundance.

3.2.1 Chain Alignment in Drawn Poly(ethylene terephthalate)

In the case of a biaxially drawn film of poly(ethylene terephthalate) (PET) from an industrial process line, the orientational distribution was mapped out in the 3D exchange NMR spectrum by flipping the sample between different orientations with respect to the magnetic field (*direction exchange with correlation for orientation distribution evaluation and reconstruction*, DECODER).²⁷ The NMR signals of the different structural units of PET are completely resolved in the

Figure 6 (a) ^{13}C CP MAS NMR spectrum of an amorphous polypropylene at $T = 252\text{ K}$ ($T_g - 6\text{ K}$).²⁴ Note that the observed splitting is due to conformational effects. (b) Schematic representation of the conformations of a tetrameric unit in polypropylene relevant for the γ -gauche effect of the methylene group C^0H_2 . One particular configuration, the mrr tetrad, is selected, here. The abbreviation $t^*.g$ stands for a conformational unit around a carbon center denoted by $\cdot$, with undefined conformations of the neighboring bonds and t and g conformations of the next-neighboring bonds

3D cube, and their orientation distributions thus separately determined.²⁸ As depicted in Figure 7(b), the chain axes are confined to the film plane (full-width at half-maximum, fwhm, of 15°), while the in-plane distribution is much broader (fwhm $\approx 90^\circ$). The planes containing the phenylene rings and the carboxyl group are oriented preferentially parallel to the plane of the film (fwhm = 55°).

Figure 7 (a) ^{13}C 3D DECODER NMR spectrum of an industrial biaxially drawn film of poly(ethylene terephthalate), (PET).²⁸ (b) Schematic representation of orientation distribution derived from it

3.2.2 Molecular Order in Liquid Crystalline Polymers

New polymeric materials often contain mesogenic groups that are able to form liquid crystalline phases.^{29,30} The interest in such liquid crystalline polymers (LCPs) comes from the fact that in the liquid crystalline phase, they can be macroscopically oriented not only by electric or magnetic fields but also by mechanical forces. The order thus generated in the mesophase can subsequently be retained in the solid material. This offers interesting applications, ranging from high-tensile-strength fibers to nonlinear optics and optoelectronics. In order to relate the material properties of LCPs to molecular structure, the degree of alignment as well as the mobility of the different structural units must be determined. This calls for highly selective analytical tools like NMR. In fact, pulsed ^2H NMR of selectively deuterated systems^{31,32} as well as multidimensional NMR³³ have provided already a wealth of information about the structure and dynamics of these systems.

As a specific example, let us consider a side group LCP as depicted in Figure 8(a). The development of such materials has been stimulated by the concept that the mesogens with their tendency to form ordered structures can be decoupled from the polymer chain with its tendency to form a random coil by inserting a flexible spacer. By advanced 3D MAS NMR of ^{13}C in natural abundance, involving rotor-synchronized detection of molecular order with sideband separation,³⁴ the alignment of all structural units can be studied simultaneously. Figure 8(b) displays a 3D MAS spectrum of the frozen smectic

Figure 8 Molecular order in calamitic liquid crystalline side group polymers: (a) spacer model; (b) 3D CP MAS NMR spectrum of ^{13}C in natural abundance; (c) order parameters of different functional groups derived from it. For details see Titman et al.³⁴

LCP aligned in the liquid crystalline phase in the magnetic field. Each dot in the spectrum corresponds to a single spinning sideband of a single resolvable carbon in the repeat unit, from which the degree of alignment of the corresponding unit can be retrieved. The results of the analysis in terms of order parameters $\langle P_2 \rangle, \dots, \langle P_8 \rangle$ are displayed in Figure 8(c). This not only reveals a pronounced order gradient from the aligned mesogen to the disordered chain, it also shows that the acrylic carbonyl group exhibits much higher order than the hydrocarbon units of the main chain. Because of its selectivity, high-resolution solid state NMR is able to reveal that the carbon–carbon bond that links the acrylic carbonyl to the main chain plays a crucial role in the decoupling of the ordered side groups from the disordered polymer chain. This information is needed to understand the differences in chain order for different backbones,³¹ and the rheological behavior³⁵ as well as the ordering behavior of mechanically deformed LC elastomers.³⁶

3.3 Molecular Dynamics

The molecular dynamics of polymer chains depend first of all on their phase structure. Most synthetic polymers are amorphous, forming a coiled shape as indicated in Figure 9(a). Stereoregular polymers can crystallize. However, owing to the enormous loss of conformational degrees of freedom, crystallization is incomplete and leads to semicrystalline materials that typically form lamellar structures, as depicted in Figure 9(b). Different aspects of the molecular dynamics are important in amorphous and semicrystalline systems, and the application of multidimensional solid state NMR has recently provided detailed information about chain dynamics for both cases.¹⁴

3.3.1 Rotational Motions in Crystalline Regions

Two-dimensional exchange NMR provides detailed information about the geometry of rotational motions. This was demonstrated, among other ways, by ^2H 2D exchange NMR of poly(vinylidene fluoride) (PVF₂).³⁷ This polymer is of particular interest because of its electrical properties.³⁸ The 2D spectrum for the crystalline α phase at 370 K, shown in

Figure 9 Schematic representation of (a) amorphous and (b) semicrystalline polymers

Figure 10(a), in addition to a well-defined powder spectrum (Pake pattern) along the diagonal, displays well-developed elliptical exchange ridges. The latter indicates jump motions of the PVF₂ chains through the crystal lattice, which interchange C– ^2H bond directions differing by 113° , in agreement with the refined crystal structure. Altogether, 16 conformational defects had previously been proposed to be responsible for the chain dynamics in this polymer. Together with knowledge of the change in dipole moment generated by the motion, a specific conformational change $tg\bar{t}\bar{g} \leftrightarrow \bar{g}tgt$ of a chain defect

Figure 10 Chain motion in the crystalline α phase of poly(vinylidene fluoride), (PVF₂).³⁷ (a) Experimental ^2H 2D exchange NMR spectrum at $T = 370\text{ K}$, mixing time $t_m = 200\text{ ms}$. (b) Geometry of the conformational jumps, T and G refer to *trans* and *gauche* conformations of the respective bonds, while A and C describe the direction of the dipole moment with respect to the a and c crystal axes

[Figure 10(b)] was identified as being responsible for the mechanical and dielectric relaxation in the crystalline regions of this polymer.³⁷

In other semicrystalline polymers like polypropylene, poly(oxyethylene), and poly(ethylene oxide), slow chain motions in the crystalline regions have been detected, and 2D exchange NMR of ^2H and ^{13}C has identified these motions as being due to helical jumps.^{12–14,39}

3.3.2 Chain Diffusion between Crystalline and Amorphous Regions

Not only can two-dimensional exchange NMR detect molecular dynamics via the resulting rotations of individual groups of the monomer unit, but it is also able to detect chain diffusion from crystalline to amorphous regions in semicrystalline polymers.⁴⁰ Although occasionally postulated,⁴¹ this process has not been accepted as a general concept, most likely because of lack of experimental evidence.

Our 2D experiment makes use of the fact that, under MAS, the all-*trans* conformation in the crystalline regions of polyethylene (PE) has an isotropic chemical shift that differs by approximately 2 ppm from that of the *gauche*-containing conformers in the amorphous regions. In the sketch of polyethylene (PE) chains in a crystallite near the interface with an amorphous region shown in Figure 11(a), carbons 1

and 2 would contribute to the “amorphous” signal [marked *a* in Figure 11(b)] and the carbons 9 and 10 would contribute to the “crystalline signal” (marked *c*). The exchange intensity between the ^{13}C signals for CH_2 groups in the crystalline and amorphous regions is clearly visible in Figure 11(b). This directly proves chain diffusion taking CH_2 groups from the crystalline into the amorphous regions and vice versa. This translational diffusion in the solid state results from the well-known α process, assigned to 180° jumps of the chain stems in the crystallites,⁴¹ accompanied by a translation by one CH_2 unit. The quantitative analysis of our 2D NMR and relaxation data yields jump rates in complete agreement with previously reported values (activation energy $E_a = 105 \text{ kJ mol}^{-1}$). It shows that the root-mean-square displacement of individual CH_2 groups amounts to more than 100 nm within 100 s near 360 K, corresponding to a translational diffusion constant of $10^{-14} \text{ cm}^2 \text{ s}^{-1}$. In commercial materials, chain diffusion, as detected here, is suppressed by branching, since it leads to deterioration of the long-term mechanical properties owing to creep.

3.3.3 Chain Motions of Amorphous Polymers at the Glass Transition

As an amorphous polymer is heated above its glass transition temperature T_g , its mechanical properties change significantly within a temperature range of typically 20–30 K where the material transforms from a glassy solid to a highly viscous melt.^{1–3,42} (An excellent overview of dynamic phenomena at the glass transition is given in special issues of the *Journal of Non-Crystalline Solids*.⁴³) However, the dynamic processes on a molecular level, responsible for these changes in the macroscopic behavior, are not sufficiently well characterized. Multidimensional exchange NMR has now provided information about the chain dynamics at the glass transition in unprecedented detail.¹⁴

Conformational (*trans*–*gauche*) transitions are usually considered as an important aspect of polymer chain dynamics in the melt and in solution.⁴⁴ Slow conformational transitions at temperatures slightly above T_g have indeed been observed in various polymers.^{24,45} This is demonstrated for aPP in Figure 12. The ^{13}C 2D exchange NMR spectrum was recorded under rapid MAS, such that isotropic lines were obtained. The conformational exchange clearly manifests itself by pronounced cross peaks between the lines corresponding to the $t^*.t$ and the $t^*.g$ conformers discussed earlier (see Figures 5 and 6).

However, as pointed out, for example, by Helfand et al.,⁴⁶ such motions need not be strictly local processes described by kink⁴⁷ or three-bond motions on a diamond lattice,⁴⁸ involving rotations by well-defined angles about spatially fixed C–C axes. Conformational transitions may also arise from relaxation processes involving longer chain units, leading to translational and angular displacements of different amplitudes of the corresponding monomer units. Indeed, ^2H 2D exchange NMR of aPP of the chain dynamics does not show any sign of preferred rotational angles.⁴⁹ As demonstrated in Figure 12(b), the ^2H spectra could be fitted adequately on the basis of an isotropic rotational diffusion model involving small angular steps.

The correlation times of the conformational dynamics agree remarkably well with those of the rotational motions. This is

Figure 11 Chain diffusion in solid polyethylene, (PE).⁴⁰ (a) Sketch of PE chains in a crystallite, near the interface with an amorphous region. (b) ^{13}C 2D MAS NMR spectrum at $T = 363 \text{ K}$; signal of the crystalline regions suppressed through single pulse irradiation. (c) Arrhenius plot of jump rates for the primary step of chain diffusion in PE

Figure 12 Chain motion of atactic polypropylene (aPP), at the glass transition. (a) ^{13}C 2D CP MAS spectrum at $T = 250\text{ K}$ ($T_g + 12\text{ K}$) and mixing time $t_m = 500\text{ ms}$. The cross peaks indicate conformational transitions.⁴⁵ (b) ^2H 2D exchange NMR spectrum at $T = 270\text{ K}$ ($T_g + 17\text{ K}$) and mixing time $t_m = 50\text{ ms}$. The broad exchange features indicate rotational motions, which can be fitted by small-angle step rotational diffusion;⁴⁹ see also the reorientational angle distribution obtained from a quantitative fit of the spectrum. (c) Mean correlation times for the various aspects of the chain dynamics in different polypropylene samples plotted versus reduced temperature from ^{13}C and ^2H NMR; for details see Zemke et al.,²⁴ Schaefer et al.,⁴⁹ and Dekmezian et al.⁵⁰

demonstrated in Figure 12(c), where mean correlation times determined by various techniques on different amorphous PP samples are shown.²⁴ Also included are values determined earlier through ^{13}C spin–lattice relaxation times by Mandelkern and co-workers⁵⁰ at elevated temperatures. All these correlation times can be fitted by the Williams–Landel–Ferry (WLF) equation⁴² describing mechanical relaxation over more than 12 orders of magnitude. Thus, as noted before,^{45,48,51} the timescales of the chain dynamics as probed for individual CH_2 units by 2D NMR are in excellent agreement with those of the collective processes responsible for the strong temperature dependence of the α process at the glass transition.^{3,42,43}

3.3.4 Geometry of Chain Motion in Amorphous Polymers

As noted in the preceding section, conformational transitions in a vitrifying melt need not be strictly local processes involving rotations by well-defined angles in a potential that is static with respect to an external reference frame. If conformational transitions do indeed arise from relaxation

processes of larger chain units⁴⁶ involving translational and angular displacements of different amplitude along such a unit then the rotational potential around a given C–C bond, which with respect to an internal frame would still look like that plotted in Figure 5(b), can be displaced by large angles after a conformational transition has occurred around that bond. Such displacements are difficult to prove experimentally. In fact, we are unaware of techniques or attempts in other groups that tackle this question. Yet it is of profound importance in order to understand the coupling of molecular dynamics and macroscopic properties such as viscosity or dynamic mechanical relaxation. Indeed, there are several ways in which such angular displacements manifest themselves in multidimensional NMR experiments.¹⁴ A particularly direct way of proving their existence is provided by 3D exchange NMR. There the orientation of a selected group is measured at three distinct points in time through their frequencies ω_1 , ω_2 , ω_3 , displaced by two mixing times t_{ma} and t_{mb} [Figure 3(a)]. If the conformational transitions occurred in a potential that was static on average, at least on the timescale of several jumps,

the groups under study should exhibit long-term orientational memory,¹⁴ which should manifest itself by jumps back to the starting orientation. These can directly be probed by 3D exchange NMR, where return jumps lead to ridges with $\omega_1 = \omega_3$.

Poly(vinyl acetate) (PVAc) provides a means to check such long-term orientational memory by 3D exchange NMR. This is due to the fact that, even in the ^{13}C NMR spectrum of a nonrotating sample, the powder pattern of the carbonyl carbon is completely separated from the signals of the aliphatic carbons. Thus it was possible to record a complete 3D exchange spectrum for that position.¹⁴ In Figure 13, it is compared with a 3D exchange NMR spectrum of poly(ethylene oxide), (PEO), a highly disordered semicrystalline polymer.⁵² In both cases, the mixing times t_{ma} and t_{mb} were set equal. The ridge in the diagonal plane $\omega_1 = \omega_3$ due to return jumps indicating long-term orientational memory is a prominent feature of the PEO spectrum [Figure 13(b)], but is absent from the PVAc spectrum [Figure 13(a)]. Thus, the disordered 7_2 helix of PEO has a finite probability to return to the start position even after numerous helical jumps,¹⁴ whereas the repeat unit of PVAc apparently loses its orientational memory at each large-angle jump. This proves that in a semicrystalline polymer the chain moves in a potential that, on average, is static, whereas no such average static potential can be associated with the chain motion of an amorphous polymer above T_g . This also means that a tight coupling of molecular and cooperative dynamics must exist in amorphous polymers.

3.3.5 Nature of Nonexponential Relaxation above T_g

The time dependence of relaxation processes in amorphous polymers above T_g cannot be described by single exponentials. This is inferred from nonexponential correlation functions measured by conventional relaxation techniques,^{42,43} and also shows up in 2D exchange NMR.^{14,49,51} This is illustrated in Figure 14 for poly(vinyl acetate), where again the carbonyl carbon only is considered.⁵³ From the ratio of diagonal and off-diagonal intensity of 2D exchange spectra as a function of t_m , the correlation function $\langle \omega(0) \omega(t_m) \rangle$ is obtained and is plotted in Figure 14(a). The nonexponential decay is consistent with a stretched exponential Kohlrausch–Williams–Watts function

Figure 13 ^{13}C 3D exchange CP NMR spectra without MAS, comparing the chain motion in an amorphous and in a crystalline polymer: (a) poly(vinyl acetate), (PVAc), at $T = 311\text{ K}$ ($T_g + 10\text{ K}$) and mixing times $t_{\text{ma}} = t_{\text{mb}} = 500\text{ ms}$; only the carbonyl region of the spectrum is shown; (b) poly(ethylene oxide), (PEO), at $T = 225\text{ K}$ and $t_{\text{ma}} = t_{\text{mb}} = 1\text{ s}$; frequency scales in (a) and (b) are different for better comparison¹⁴

$\exp [-(t/\tau_0)^\beta]$ ^{54,55} with a mean correlation time $\tau_0 = 20\text{ ms}$ and $\beta = 0.3$, which translates into an asymmetric distribution of correlation times with a width of approximately three decades, as plotted in Figure 14(b).

The nature of such observations has been a matter of dispute for a long time. Two conflicting views offer explanations in terms of (i) a spatially heterogeneous distribution of correlation times (parallel processes, nonergodic) or (ii) an intrinsically nonexponential loss of correlation in a homogeneous system (a serial process, ergodic). Experimental techniques that are able to distinguish these views on a timescale relevant for the glass process, i.e., a second or so, were lacking. This distinction can be achieved by multidimensional exchange NMR, where the orientation of the same molecule can be measured by three or more subsequent points in time. In the reduced 4D exchange experiment [Figure 14(c)], we keep the first two evolution times t_1 and t_2 constant and equal. Units for which $\omega(\theta_1) = \omega(\theta_2)$, i.e., that have the same orientation before and after t_{ma} , generate a stimulated echo. The magnetization generated by the ‘slow molecules’ is then stored by a 90° pulse, and a 2D exchange spectrum of that selected subensemble of slow molecular units is recorded at later times, after t_{mb} , constituting a reduced 4D exchange spectrum.

In Figure 14(d)–(f), two reduced 4D exchange spectra are compared with a reference 2D NMR spectrum. The mixing times t_{ma} and t_{mc} were kept equal and comparable to τ_0 . Whereas the 2D spectrum for that mixing time [Figure 14(d)] is a superposition of a diagonal ridge and broad exchange features, the reduced 4D spectrum for $t_{\text{mb}} = t_{\text{ma}} = t_{\text{mc}}$ exhibits the diagonal ridge only [Figure 14(e)]. This proves directly that the system is heterogeneous (nonergodic) on the timescale of the mean correlation time τ_0 , since the spectrum of the selected subensemble is entirely different from that of the total ensemble. However, on lengthening t_{mb} by two orders of magnitude (point V in Figure 14(b)), considerable off-diagonal intensity is observed [Figure 14(e)]. This means that a significant number of units that were slow initially ($\tau \gg \tau_0$) have changed their correlation time to $\tau < \tau_0$. Thus, in the vitrifying melt, fluctuations are detected that change the reorientational dynamics of chain units. Markedly, these fluctuations causing the system to become homogeneous (ergodic) occur on timescales within the “long-time tail” of the distribution of correlation times. These experiments clearly show that, during the glass transition, the molecular units undergo non-Markovian motion with time-dependent correlation times, though not on the timescale of the mean correlation time but rather in a process limiting the longest correlation time.

3.3.6 Local Motions in the Glassy State and Their Relation to Mechanical Properties

The favorable mechanical properties of glassy polymers stem from relaxation processes that are possible even in the solid state.^{2,3,42} However, little is known about the geometry of molecular dynamics responsible for such processes. Mechanical measurements^{56,57} and ^2H 1D NMR⁵⁸ have previously established a connection between the low-temperature γ relaxation and phenylene ring motions in polycarbonate (PC), a polymer with especially favorable mechanical properties. The ring motion was identified as a flip by 180° [Figure 1(f)]. This was subsequently verified by ^{13}C NMR.^{59,60} However,

Figure 14 Nature of nonexponential loss of correlation above the glass transition.⁵³ (a) Nonexponential decay of correlation function with experimental points for poly(vinyl acetate), (PVAc). (b) Distribution of correlation times $G(\tau)$ derived from it. (c) Pulse sequence for reduced 4D exchange NMR. (d) Experimental and simulated ^{13}C 2D exchange NMR spectrum at $T = 320\text{ K}$ ($T_g + 20\text{ K}$) and mixing time $t_m = 10\text{ ms}$. (e) Experimental and simulated ^{13}C reduced 4D exchange NMR spectrum at the same temperature and mixing times $t_{ma} = t_{mb} = t_{mc} = 10\text{ ms}$. (f) Similar to (e), but with $t_{mb} = 1\text{ s}$ and $t_{ma} = t_{mc} = 10\text{ ms}$

the NMR lineshapes are unable to provide information about the detailed geometry of the phenylene motion at low temperatures, where it occurs on a timescale of hundreds of milliseconds, which can be probed directly by mechanical relaxation experiments. Again, such slow molecular dynamics can be detected by 2D exchange NMR, as demonstrated in Figure 15. The ^2H 2D exchange NMR spectrum of a sample selectively deuterated at the phenylene rings, PC- d_4 , exhibits somewhat broadened elliptical ridges [Figure 15(a)],⁶¹ which confirm the geometry of the phenylene motion as rotations around the *para* axis as indicated. However, the flip typically does not involve a rotation by exactly 180° , but by angles that can differ substantially from this mean value [Figure 15(b)]. This means that, after a rotation, the phenylene group finds itself in a slightly different environment, which readily explains the connection between this molecular dynamic process and the mechanical relaxation. Indeed, when the 2D spectrum is recorded under tensile stress, such that the sample is stretched up to the nonlinear region, yet below the yield point, the angular uncertainty in the flip angle increases further⁶¹ [Figure 15(b)]. This is consistent with the reported increase in the strength of the mechanical relaxation under such conditions.⁶² The timescale of the phenylene flips is not uniform but displays a broad distribution of correlation times⁶³ reflecting different activation energies in different regions of the sample.

3.3.7 Geometry of Side Group Motion in the Glassy State

The β relaxation observed in poly(methyl methacrylate), (PMMA), by means of both dielectric and dynamic-mechanical relaxation,³ is often considered as the archetype of a localized (β) relaxation in polymers. Since this relaxation is very prominent in dielectric relaxation, it has traditionally been attributed to the carboxyl side group with its large dipole moment [Figure 16(a)]. However, quantitative analysis of relaxation strengths in both techniques is virtually impossible. Thus, neither was the geometry of the side group motion known, nor whether all or only a fraction of the groups are participating in the motion in the glassy state. A study involving both ^{13}C and ^2H multidimensional exchange NMR gave answers to these questions.⁶⁴ In fact, the geometry of the side group motion turned out to be more complex than originally anticipated. It involves ill-defined flips by $180^\circ \pm 20^\circ$ about the C–C bond linking the carboxyl side group to the polymer backbone. This flip motion is coupled to a “rocking” motion about the local chain axis [Figure 16(a)], with a 20° root-mean-square amplitude. This motion can be detected in both ^{13}C and ^2H NMR, whereas the flip shows up only in the ^{13}C spectra. In the latter, the two coupled motional processes manifest themselves in the unstructured exchange intensity covering most of the 2D plane [Figure 16(b)], whereas the angular more restricted “rocking” motion leads to the exchange intensity in the ^2H spectrum being restricted to the vicinity of the diagonal⁶⁴ [Figure 16(c)].

Figure 15 Phenylene motion and mechanical behavior in bisphenol-A-polycarbonate, (PC)⁶¹. (a) ^2H 2D exchange NMR spectrum of phenylene deuterated sample at $T = 223\text{ K}$, mixing time $t_m = 500\text{ ms}$. The elliptical figures (see inset) correspond to $\Phi = 180^\circ \pm 25^\circ$ phenylene flips with reorientational angle distributions shown in (b). (c) After application of 50 MPa stress, a significant broader distribution of flip angles around the same mean 180° is observed

These findings are ascribed to the fact that the asymmetric side group, after the flip, does not fit into its original environment as depicted in Figure 16(d). Remarkably, the side group exhibits long-term orientational memory. As checked by ^{13}C 3D exchange NMR, despite the featureless exchange intensity in the 2D spectrum, the reorientation of each segment involves only two, relatively well-defined, potential energy minima. Thus, after two subsequent flips, the carboxyl group is back to almost the initial orientation [Figure 16(d)]. It is also important to realize that in the glassy state of PMMA, only about 50% of the side groups can undergo this motion. Since the side group flip requires the “rocking” motion around a locally extended chain axis, this was related to the fraction of syndiotactic triads in this polymer, which indeed favor extended conformations.⁶⁴

This example demonstrates how complex a seemingly simple side group motion in a glassy polymer can be. The complex geometry of the side group dynamics stems from its asymmetry, since the packing apparently does provide enough free volume for a methyl group, in which it could fit after a flip. Obviously, this finding should be of interest not only for

Figure 16 Side group motion in poly(methyl methacrylate), (PMMA).⁶⁴ (a) Sketch of the PMMA geometry and the principal axes for ^{13}C (carboxyl group) and ^2H (O-methyl group) NMR. (b) ^{13}C 2D exchange NMR spectrum at $T = 333\text{ K}$ and mixing time $t_m = 50\text{ ms}$. (c) ^2H 2D exchange NMR spectrum at $T = 355\text{ K}$ and mixing time $t_m = 500\text{ ms}$. (d) Sketch of the dynamics of an asymmetric side group in its correspondingly asymmetric environment, indicating that in order to fit the asymmetric side group into the volume that it had occupied before the flip, a twist around the local chain axis (“rocking” motion) is required

the understanding of the relation between molecular dynamics and the mechanical properties of amorphous polymers, but also in biophysics, where motions of asymmetric side groups are common dynamic processes, e.g., in proteins.⁶⁵

3.4 Heterogeneous Polymers

In heterogeneous polymers, i.e., polymer blends or block copolymers,^{1,2} domain sizes, or structures on the scale from a few to some tens of nanometers, can be investigated by NMR spin diffusion experiments. Thus, NMR is particularly suited for characterizing small domains, nanoheterogeneities, or concentration fluctuations on lengthscales of a few nanometers, where other methods often fail owing to limitations in resolution or contrast. Thus, spin diffusion measurements are well established in solid state NMR of polymers.⁸ Moreover, several advanced approaches exploiting ^1H spin diffusion with highly selective ^{13}C detection have been introduced.¹⁴

3.4.1 Wideline Separation Experiments on Polymer Blends

Spin diffusion experiments require that the different components contained in the sample be distinguished in their

NMR parameters. This is particularly straightforward if the components differ in their mobility. In fact, a long-standing method for a qualitative characterization of molecular mobility is ^1H wideline NMR spectroscopy.⁸ There, rapid large-amplitude motions are detected through the reduction of dipolar linewidths. However, 1D proton lineshapes leave many questions open, since they typically represent superpositions of broad and narrow lines, and their relation to different structural units is often not obvious. In a straightforward combination of ^1H wideline NMR, cross polarization and ^{13}C MAS spectroscopy in a 2D experiment,⁶⁶ it is possible to separate the dipolar patterns for the different structural units (wideline separation, WISE).

The power of this technique is demonstrated in Figure 17, where data on a 50:50 wt% blend of polystyrene, (PS), and poly(vinyl methyl ether), (PVME), cast from toluene, are presented. This blend appears homogeneous by most classical techniques. The ^1H wideline spectrum [Figure 17(a)] consists of a rather featureless superposition of components with different dipolar linewidths, which are nicely separated in the second frequency dimension [Figure 17(b)] and related to their ^{13}C chemical shifts. Substantial motional heterogeneities, PVME being more mobile than PS, are detected despite the fact that the spectrum is recorded about 60 K above the calorific glass transition of the blend. By introducing a mixing time⁶⁶ to allow for spin diffusion, the ^1H lineshapes equilibrate after only 5 ms [Figure 17(c)]. From this, the domain sizes for the regions of different mobility were estimated to be 3.5 ± 1.5 nm. Thus, these advanced NMR techniques reveal substantial motional differences in different regions of this blend, which rather than homogeneous should better be described as nanoheterogeneous.

3.4.2 Domain Sizes from Spin Diffusion Experiments

Another advanced approach towards quantitative use of spin diffusion experiments exploits ^1H spin diffusion after high-resolution ^1H solid state NMR by combined rotation and multiple-pulse spectroscopy (CRAMPS), with high-resolution ^{13}C MAS detection.^{14,16} In a particularly clear-cut case, this technique has been applied to a series of symmetric diblock copolymers of PS and PMMA.¹⁶ In Figure 18(a), the increase

(a) Conventional ^1H wideline spectrum of a blend of polystyrene, (PS), and poly(vinyl methyl ether), (PVME). (b) 2D ^1H ^{13}C WISE NMR spectrum at $T = 320$ K, note the different ^1H linewidths for PS and PVME. (c) Similar to (b), but with spin diffusion over a time $t_m = 5$ ms; note that now all lines have equal ^1H linewidths

Figure 18 Spin diffusion as a tool for determining domain sizes in heterogeneous polymers.¹⁶ (a) ^{13}C MAS spectra of the symmetric diblock copolymer PS-*b*-PMMA as a function of the diffusion time t_m after selection of proton magnetization of the methoxy group in PMMA. (b) Signal intensity of the phenyl carbons in PS as a function of t_m for different molecular weights. The numbers indicate the domain sizes obtained from the respective fits

in the carbon signal of the phenyl ring in the PS block after selection of the PMMA block is plotted against the spin diffusion time t_m for various block lengths. The equal lengths of both blocks in the symmetric copolymer ensures a lamellar structure, which makes quantitative analysis of the data easy. PMMA and PS are known to be immiscible. The spin diffusion data yield domain sizes that are consistent with the scaling law $M_n^{0.66}$, where M_n denotes the molar mass of the block, as predicted theoretically.² For comparison, a statistical copolymer, in which no phase separation is possible, and a blend of both homopolymers were included in the data set. The close agreement between experimental intensities and the time dependence calculated from the diffusion equation is apparent in Figure 18(b), and demonstrates that domain sizes between 0.5 and 100 nm can be determined quantitatively.

3.4.3 Packing and Mobility in Rigid Rod Systems

Advanced solid state NMR has also been applied to study the structure and dynamics of advanced polymer materials.³³ As a specific example, consider rigid rod systems consisting of *para*-substituted aromatics as stiff macromolecules, such as polyesters, polyamides and polyimides. These have attracted

Figure 19 2D WISE NMR spectra of aliphatic side chains of various rigid rod macromolecules and structural models derived from them and spin diffusion measurements:⁶⁹ (a) polyester, A-form, PPTE-A; (b) polyimide PPPI; (c) polyamide, PPTA

considerable interest because of their unusual mechanical properties.⁶⁷ When processed from a nematic mesophase, the parallel packing of the stiff macromolecules results in high-modulus fibers. In order to increase the processability of such materials, flexible side chains are attached. However, owing to the inherent incompatibility of stiff backbone and flexible side chains, layer structures are formed where these different building elements are separated⁶⁸ (see Figure 19). Depending on the packing requirements of the stiff macromolecules, highly crystalline [form B, Figure 19(b)] or disordered amorphous [form A, Figure 19(a) and (c)] structures are formed. This imposes packing restrictions on the side chains, favoring crystallization or preventing it. Whereas X-ray scattering has been invaluable in establishing the basic features of the packing, it is difficult to provide clear-cut information about the details of the molecular organization in such complex systems.

Here, advanced 2D solid state NMR methods offer interesting alternatives. Figure 19 displays the results of 2D WISE NMR and spin diffusion experiments⁶⁹ on the side chains of a polyester (PPTE-A), a polyimide (PPPI), and a polyamide (PPTA). A high-resolution ^{13}C CP MAS spectrum of the polyimide is also displayed as an insert. The ^1H wide-line spectra reflect the molecular dynamics of the different methylene groups. They are superpositions of broad and narrow components, even at the chain end (C_{16}). The different side-chain packings of the three systems—almost homogeneous

with rather extended chain in the polyester PPTE-A, separated crystalline regions with all-*trans* chains and amorphous regions with disordered chains in the polyimide PPPI, and separated regions with extended and disordered chains in the polyamide PPTA—are nicely reflected in the different WISE NMR spectra.⁶⁹

The delicate balance between the organization of the incompatible rigid main chains and flexible side chains in their respective layers thus leads to a considerable variety in the packing. Advanced NMR techniques yield specific information supplementing computer-aided X-ray studies, because NMR is sensitive to conformation, mobility, and spatial proximity of different structural elements.

4 CONCLUSIONS

High-resolution NMR in liquids is an indispensable analytical tool for structural characterization in chemistry, including the stereochemistry of polymers. Particularly in biochemical applications, the necessary spectral resolution can only be achieved, however, by two- and higher-dimensional spectroscopy. An analogous situation is encountered in solid polymers. Unless isotopic labeling is employed, the different anisotropic spin interactions can be separated only via multidimensional techniques. Besides providing highly selective structural information, advanced solid state NMR

offers unique possibilities for characterizing slow molecular dynamics and relating it to macroscopic material behavior.

1 INTRODUCTION

Molecular motion in liquids results in a time dependence of the dipolar coupling between two spins, which gives rise to transitions between the nuclear spin states. These transitions constitute the basis of the nuclear Overhauser enhancement (NOE) effect, which has long been one of the NMR cornerstones for the study of molecular structure.¹ As discussed in *NOESY*, the transition rates are determined by the square of the dipolar coupling, i.e., by r^{-6} , where r is the internuclear distance, by the angular Larmor frequency ω_0 , and by the decay constant τ_c of the autocorrelation function of the time-dependent dipolar coupling $D(t)$. In conventional homonuclear NOE experiments, the change in z magnetization of a spin B is monitored after the z magnetization of a spin A in its immediate vicinity has been perturbed. Provided τ_c is known, the rate at which the longitudinal magnetization of spin B changes after perturbing the z magnetization of A provides a measure of r . For $\omega_0\tau_c < 1.12$, the z magnetization of spin B will increase to a value higher than its Boltzmann equilibrium value when saturating the resonance of A (positive NOE), whereas the opposite holds for $\omega_0\tau_c > 1.12$. For many interesting molecules of intermediate size (500–2000 Da), the product $\omega_0\tau_c$ is frequently found to be close to 1, resulting in very small NOE effects.

As outlined above and described in detail elsewhere,^{1–4} the NOE is a cross-relaxation effect between longitudinal components of nuclear spin magnetization. In 1983, Bothner-By and co-workers developed a different type of NOE experiment, which measures cross relaxation between magnetization components that are perpendicular to the static magnetic field.⁵ The original name of this experiment is cross relaxation appropriate for *minimolecules emulated by locked spins*, or CAMELSPIN, but it is more commonly known as ROESY, for *rotating-frame Overhauser enhancement spectroscopy*. As implied in the original acronym of this experiment, the transverse cross relaxation is positive for all values of the rotational correlation time, i.e., it is the same as that found for small molecules in the NOESY experiment. The original motivation for this experiment was to study the structure of intermediate size molecules, which have near-zero longitudinal NOE effects. However, as pointed out in the original report,⁵ the

positive sign of the ROE effect also allows one immediately to distinguish cross relaxation from chemical exchange effects, which are always negative. This latter application has proven critical, for example, in studying hydration of proteins.^{6,7} Other important applications lie in the area of macromolecular structure determination, where the rotating frame Overhauser enhancement, owing to its positive sign, tends to be far less susceptible to spin diffusion effects than its longitudinal counterpart.^{8,9} Although for macromolecules, the inherent sensitivity of the ROESY experiment is less than for NOESY, numerous useful applications to proteins and nucleic acids have been reported. In addition to the nonselective ROESY experiment, a number of very interesting selective variants have been developed that can selectively probe small subsets of the Redfield cross-relaxation matrix. These elegant ROESY variants are particularly powerful for probing cross correlation,^{10–12} and they have been treated and reviewed in great detail by Bull.¹³ The discussion below is restricted to the more commonly used nonselective ROESY experiments and their various applications.

2 PRINCIPLES OF ROTATING FRAME OVERHAUSER SPECTROSCOPY

The state of a spin system is most conveniently described by the density matrix $\hat{\rho}$. For a system of two spin- $\frac{1}{2}$ nuclei, A and X, $\hat{\rho}$ is a simple 4×4 matrix. Its diagonal elements, ρ_{11} , ρ_{22} , ρ_{33} , and ρ_{44} correspond to the populations of energy levels 1, $\dots$, 4. An off-diagonal element such as ρ_{12} represents the coherence or transition between levels 1 and 2, etc. In order to describe relaxation phenomena, the Hamiltonian is usually split into a spin-dependent part $\hat{\mathcal{H}}_S$ and a spin–lattice coupling $\hat{\mathcal{H}}_{SL}$. The spin-dependent component $\hat{\mathcal{H}}_S$ consists of the Zeeman coupling to the main external magnetic field ($\hat{\mathcal{H}}_0$) plus other, much smaller, purely spin-dependent components ($\hat{\mathcal{H}}_1$) such as chemical shift, J coupling, and coupling of the spins to radiofrequency (rf) fields. The spin–lattice part $\hat{\mathcal{H}}_{SL}$ describes the coupling of the spins to the external heat bath, which is a stochastic process. Transformation into the interaction frame makes the Zeeman term $\hat{\mathcal{H}}_0$ disappear in explicit form from the Hamiltonian, and hides it as a time dependence of the operators and the density matrix. In this interaction frame and under a number of approximations, the time dependence of the density matrix $\hat{\rho}$ is then described by

$$\frac{d\hat{\rho}(t)}{dt} = -i[\hat{\mathcal{H}}_1, \hat{\rho}] - \hat{R}\hat{\rho} \quad (1)$$

$\hat{R}$ is the Redfield relaxation matrix, which describes the return to equilibrium of the spin system. The relation between its elements and the spectral densities is described in detail in *Relaxation Theory: Density Matrix Formulation*. A product $R_{1213}\rho_{13}$, for example, describes the loss per unit time of the density matrix element ρ_{12} caused by the matrix element ρ_{13} . It is important to realize, however, that relaxation is usually a slow process relative to evolution under the static Hamiltonian. Consequently, cross relaxation can only occur if the off-diagonal elements ρ_{12} and ρ_{13} oscillate at nearly the same frequencies in the laboratory frame, i.e., if the corresponding resonances overlap. In this case, the

cross relaxation between the 1–2 and the 1–3 transitions is termed a secular process. If their frequencies are different, the exchange of magnetization is a nonsecular process, and can be neglected. ROESY and its selective variants all rely on modifying the spin Hamiltonian $\hat{\mathcal{H}}_1$ in such a manner that cross relaxation can be probed between transitions that would differ in frequency in the absence of radiofrequency irradiation. In the standard ROESY experiment, this is accomplished simply by the application of a strong monochromatic rf field, which locks all magnetization that is parallel to it and dephases any perpendicular components. Neglecting off-resonance effects, the cross-relaxation rate for magnetization components locked along the rf field is therefore identical to the cross relaxation between the transverse magnetization components of two exactly overlapping resonances (identical spins).

Following Bothner-By et al.,⁵ the time dependence of the spin locked magnetization components m_A and m_B of two homonuclear spins A and B is described by

$$\frac{dm_A(t)}{dt} = -R_{2A}m_A(t) - R_{AB}m_B(t) \quad (2a)$$

$$\frac{dm_B(t)}{dt} = -R_{AB}m_A(t) - R_{2B}m_B(t) \quad (2b)$$

where R_{AB} is the cross-relaxation rate of interest, and R_{2A} and R_{2B} are the autorelaxation rates, describing the loss of magnetization, which also includes processes other than cross relaxation between spins A and B. For convenience, we assume below that $R_{2A} = R_{2B} = R_2$, which results in a particularly simple solution of equations (2a) and (2b). If two experiments are done, one with $m_A(0) = m_B(0) = 1$ and one with $m_A(0) = -m_B(0) = 1$ (for example, by selectively inverting the magnetization of spin B immediately prior to a nonselective 90°_x pulse, which is followed by a y -axis spin lock), the time dependence of $m_A(t)$ and $m_B(t)$ in these two cases is given by

$$m_A(t) = m_B(t) = \exp[-(R_2 + R_{AB})t] \quad (3a)$$

$$m_A(t) = -m_B(t) = \exp[-(R_2 - R_{AB})t] \quad (3b)$$

The difference between equations (3a) and (3b) represents the ROE, which has a maximum value for

$$t = \frac{1}{2R_{AB}} \ln \frac{R_2 + R_{AB}}{R_2 - R_{AB}} \quad (4)$$

In the isolated spin pair approximation, R_2 and R_{AB} are given by

$$R_2 = \frac{\gamma^4 h^2 (\mu_0/4\pi)^2}{80\pi^2 r^6} [5J(0) + 9J(\omega_0) + 6J(2\omega_0)] \quad (5)$$

$$R_{AB} = \frac{\gamma^4 h^2 (\mu_0/4\pi)^2}{80\pi^2 r^6} [4J(0) + 6J(\omega_0)] \quad (6)$$

where r is the internuclear distance and, for protons, $\gamma^4 h^2 (\mu_0/4\pi)^2 / 80\pi^2 = 2.84 \times 10^{10} \text{ s}^{-2} \text{ \AA}^6$. The reduced spectral density function $J(\omega)$ for isotropically reorienting molecules is defined as

$$J(\omega) = \frac{\tau_c}{1 + \omega^2 \tau_c^2} \quad (7)$$

Figure 1 (a) Maximum obtainable ROE enhancement $ROE_{\max}$ in the isolated two-spin pair approximation, assuming that the spins are relaxed exclusively by homonuclear dipolar interactions. (b) The ratios of the cross relaxation rates in the laboratory frame, R_{AB}^L , and in the rotating frame, R_{AB} , as functions of $\omega_0 \tau_c$

The maximum Overhauser enhancement obtainable for this isolated two-spin pair, using the ROE mixing time of equation (4), is shown graphically in Figure 1(a). In practice, the isolated spin pair approximation is usually not valid, and frequently R_2 is much larger than R_{AB} . In this case, it follows from equation (4) that the maximum ROE effect is obtained for

$$t \approx 1/R_2 \quad (8)$$

which means that the highest sensitivity is obtained for a mixing period on the order of the transverse relaxation time T_2 , as measured, for example, by a selective spin echo experiment.

3 COMPARISON WITH LABORATORY FRAME NOE

In the isolated spin pair approximation and assuming rigid body motion, comparison of the ROE and NOE results is straightforward. The ROE build-up rate follows directly from equation (6), and the analogous cross-relaxation rate in the laboratory frame is given by

$$R_{AB}^L = \frac{\gamma^4 h^2 (\mu_0/4\pi)^2}{40\pi^2 r^6} [6J(2\omega_0) - J(0)] \quad (9)$$

Figure 1(b) shows the ratio of the cross-relaxation rates in the laboratory and rotating frames as a function of $\omega_0 \tau_c$. For

$\omega_0\tau_c \ll 1$, the build-up rates are nearly identical, whereas in the slow motion limit ($\omega_0\tau_c \gg 1$) R_{AB} approaches $-2R_{AB}^L$. Because of the dependence of R_{AB}^L/R_{AB} on $\omega_0\tau_c$, this ratio in principle can be used directly to determine the rotational correlation time τ_c , allowing one to derive absolute interproton distances from either R_{AB}^L or R_{AB} .¹⁴ In practice, the use of this approach is limited to the region $0.3 < \omega_0\tau_c < 3$, where the ratio R_{AB}^L/R_{AB} has its steepest dependence on τ_c . A second potential problem with this approach is caused by rapid internal motion, such as methyl group rotation, which also affects R_{AB}^L/R_{AB} .¹⁵

3.1 Sensitivity Considerations

Although the cross-relaxation rate in the rotating frame is always higher than in the laboratory frame, this does not mean that the sensitivity of the ROESY experiment is always greater than for NOESY. The relative sensitivity of the two experiments can be derived by calculating the spectra obtained for mixing times that maximize the cross-peak intensity. As seen from equation (4), for the ROESY experiment this optimum mixing time depends on the transverse magnetization leakage rate R_2 , and for the NOESY experiment it depends on the longitudinal leakage rate R_1 . Neglecting the effect of the different NOESY and ROESY mixing times on the total duration of each experiment, the sensitivity ratio ξ of the NOESY versus the ROESY experiment has been calculated by Farmer et al.^{15,16} for two different external relaxation rates R_{ext} , and is shown in Figure 2. This figure suggests that the ROESY experiment is expected to yield higher sensitivity

than the NOESY experiment over a wide range of rotational correlation times. There are several practical reasons that reduce the sensitivity advantage of ROESY over NOESY, however. For example, off-resonance effects reduce the cross-relaxation rate in the ROESY experiment,^{10,14–17} and so do spurious coherent Hartmann–Hahn magnetization transfer processes,¹⁸ both discussed in some more detail below. Also, Figure 2 assumes that the external relaxation contribution R_{ext} , which represents the leakage rate from mechanisms other than homonuclear dipolar interactions, is identical for R_1 and R_2 . For macromolecules, this approximation may not be valid, since proton chemical shift anisotropy and heteronuclear dipolar coupling have far larger effects on R_2 than on R_1 . For $\omega\tau_c > 1.12$, there also is a third reason: because of the negative sign of the NOE, indirect contributions to the NOE cross peak increase its intensity. The opposite holds for the ROESY experiment, where the positive sign of the ROE causes the indirect contribution, relayed via one spin, to be opposite in sign to the direct contribution (the so-called three-spin effect). Indirect contributions therefore attenuate the cross-peak intensity in the ROESY spectrum and, for $\omega_0\tau_c > 1.12$, they increase the cross-peak intensity in NOESY.

3.2 The Effect of Internal Motion

In both the NOESY and ROESY experiments, cross-relaxation and leakage rates are strongly influenced by rapid internal motions. These internal motions change the shape of the spectral density function and constitute a major obstacle when attempting to derive accurate internuclear distances from the cross relaxation rates. In the model-free approach for rapid internal motion,^{19,20} the spectral density function $J(\omega)$ becomes

$$J(\omega) = \frac{S^2\tau_c}{1 + \omega^2\tau_c^2} + \frac{(1 - S^2)\tau}{1 + \omega^2\tau^2} \quad (10)$$

where S^2 is the generalized order parameter, τ_c is again the molecular rotational correlation time, and $1/\tau = 1/\tau_e + 1/\tau_c$, with τ_e the effective correlation time of any internal motions. If S^2 and τ_e are known, equation (10) can be substituted directly into equation (6). In practice, however, detailed knowledge of S^2 and τ_e is rarely available. Note that S^2 would need to be known for every proton pair; assuming ‘rigid’ protons A and X and a third proton M, subject to restricted internal mobility, the order parameters for A–M and M–X interactions are likely to have different values. However, it is clear from equations (6) and (10) that rapid internal motion ($\omega_0\tau_e \ll 1$) reduces the rotating frame cross-relaxation rate. When using only a single mixing time for estimating the ROE cross-relaxation rate, the error in the linear build-up approximation also reduces the rotating frame cross-relaxation rate. Provided τ_c is known, measurement of R_{AB} therefore yields an upper limit distance constraint that is at least as large as the true interproton distance, and the errors merely weaken the constraint that is being used. In contrast, indirect NOE effects (spin diffusion) can be a major problem when using NOESY to study macromolecular conformation, since they can result in a very significant underestimate of the upper limit for the interproton distance. Such an underestimate can actually result in distorted structures.

Figure 2 The ratio of the maximum cross-peak magnitude for NOESY compared with ROESY, ξ , as a function of the rotational correlation time τ_c for an AX spin system with interatomic distance $r_{AX} = 0.3$ nm. Plots are shown for Larmor frequencies of 300 MHz (—) and 500 MHz (---) and for two different external relaxation rates R_{ext} . R_{ext} represents contributions to the leakage rate from sources other than homonuclear dipolar interactions. R_{ext} was assumed to be independent of τ_c , and identical for NOESY and ROESY. Reproduced, with permission, from Farmer et al.¹⁵

Because of the positive sign of the ROE, indirect ROE effects generally result in a reduction in cross-peak intensity, or even in a sign change (three-spin effect), which does not result in too tight a distance constraint. As a rule of thumb, interproton distances larger than 0.35 nm rarely give rise to observable ROE cross peaks. This can, of course, also be considered to be a disadvantage, since it results in a much smaller set of interproton distance constraints. It has been suggested that for protein structure determination, the number of constraints is more important than their precise values.²¹

3.3 Equivalent Spins

Farmer et al.¹⁵ provide a detailed discussion of the effect of equivalent spins on NOE and ROE cross-relaxation and leakage rates. For methyl groups, for example, they show that the very rapid cross relaxation among the equivalent methyl protons can lead to a dramatic increase in the leakage rate, which adversely affects the maximum obtainable ROESY cross-peak intensity. Note that intramethyl group cross relaxation does not contribute to the leakage term in the NOESY experiment. In the absence of rapid methyl group rotation and for long τ_c values (>30 ns), the maximum obtainable ROESY intensity becomes more than an order of magnitude less sensitive than for NOESY. Rapid methyl group rotation ($\tau_e < 1$ ns) quenches the intramethyl group cross relaxation, however, and NOESY and ROESY are then again of comparable sensitivity.¹⁵ In contrast to methyl groups, methylenes are not usually subject to extensive internal dynamics, resulting in a high leakage rate in the slow tumbling limit. Cross peaks reach a maximum intensity for short mixing times, and the sensitivity of the ROESY experiment is reduced.

4 EXPERIMENTAL REALIZATION

A variety of different experimental schemes have been proposed for recording ROESY spectra. Some of the more popular ones are sketched in Figure 3, and these are briefly discussed below. The pulse schemes of Figure 3(a) and (b) are the original 1D and 2D methods for recording CAMELSPIN/ROESY spectra.⁵ In (a), a selective 180° pulse inverts the z magnetization of a preselected resonance on alternate scans. After a subsequent 90°_x pulse, a strong monochrome radiofrequency field (SL_y) locks the spins along the y axis, and cross relaxation takes place. Subtracting odd-from even-numbered transients, recorded with and without selective inversion of the preselected resonance, yields the 1D difference spectrum, which shows intensity for spins that cross relax with the inverted spin. Figure 3(b) is the simple 2D analog of the 1D experiment, where frequency labeling is accomplished by a 90° pulse followed by the variable evolution period t_1 , instead of the selective pulse.

As discussed below, for minimizing homonuclear Hartmann–Hahn transfer during the application of the spin lock field, it is necessary that the effective spin lock field for J coupled spins be different.¹⁸ This can be accomplished either by using a relatively weak rf field strength or by positioning the rf carrier at one side of the spectrum. In this case, the effective field makes an angle θ with the z axis, and only a fraction $\sin \theta \cos \omega_A t_1$ of the A-spin magnetization is locked along the

Figure 3 Experimental schemes for recording ROESY spectra. (a) One-dimensional scheme. (b) Original two-dimensional scheme. (c) Scheme with 90°_y pulses bracketing the y axis spin lock, to avoid signal loss caused by off-resonance spin locking. (d) Spin lock with small-angle ($\alpha \approx 30^\circ$) pulses, separated by short delays, and bracketing pulses. (e) Spin lock with phase ramping of the α pulses. If $N \Delta\phi = 2\pi$, the total number of α pulses needs to be an integral multiple of N . The delay between the 90°_y and the first α pulse, and between the last α pulse and the following 90°_y pulse, needs to be half the duration of the α pulse spacing τ_d . Phase ramping merely serves to obtain the same effect as moving the carrier by $\Delta\phi/(\tau_p + \tau_d)$, where τ_p is the duration of the α pulse, from its actual position during the spin lock, without introducing problems related to phase continuity. (f) Same as (e), but using a continuous spin lock. (g) Transverse spin lock, where the spins are ‘locked’ along an axis perpendicular to the axis (x) along which the pulses are applied. For minimizing homonuclear Hartmann–Hahn contributions, the carrier position and rf amplitude need to be adjusted for schemes (a)–(d), and the phase-ramp-generated offset needs to be adjusted for schemes (e) and (f). To avoid excessive sample heating, the power used during the mixing period in schemes (e)–(g) may also need to be reduced. For the 2D schemes (b)–(g), quadrature in F_1 is obtained by changing the phase of the first pulse in the standard States,²² TPPI,²³ or States–TPPI²⁴ manner

Figure 4 Definition of the effective field direction v_{eff} for spin A at resonance offset $\omega_A/2\pi$, during irradiation with an rf field of strength v along the y axis. Before the spin lock field is turned on, the transverse magnetization of A, M_A , is in the (x,y) plane

effective field (Figure 4), where ω_A is the angular resonance frequency of spin A. After the spin lock field is turned off, only a fraction $\sin \theta$ of the spin locked magnetization is present in the transverse plane, and the sensitivity of the experiment is effectively reduced by $\sin^2 \theta$. This off-resonance loss can be avoided if the weaker spin lock field is bracketed by nonselective 90°_y pulses (Figure 3c).²⁵ In this case, a fraction $\sin(\omega_A t_1 + \theta)$ of the transverse A-spin magnetization will be spin locked along the effective field. At the end of the ROESY mixing period, all spin locked magnetization is returned to the transverse plane by the final 90°_{-y} pulse. The loss in signal by a factor $\sin^2 \theta$, as applies to the scheme in Figure 3(b), is now transferred into a phase error θ in both the F_1 and F_2 dimensions of the spectrum. To a good approximation, the phase error θ depends linearly on the resonance offset, and a first-order frequency-dependent phase correction can be used to compensate for it. Note that no phase cycling of the 90°_y pulses relative to the y axis spin lock should be used, since inverting the phase of this pulse to 90°_{-y} would also invert the phase error. Co-adding the spectra would then remove the phase error and reintroduce the amplitude loss.

The use of a low-power spin lock mixing period requires the capability to rapidly change the rf power level, which may constitute a problem on older spectrometers. This problem can be avoided by replacing the continuous spin lock by a series of closely spaced high-power pulses (Figure 3d), each of a small flip angle ($\sim 30^\circ$).²⁶ If the flip angle of the short pulse is α , and M pulses are applied per second, this irradiation is equivalent to spin locking with a continuous rf field of $M\alpha/2\pi$ (in Hz), provided that M (in Hz) $\gg \delta_{\text{max}}$, where δ_{max} is the maximum offset of a resonance of interest from the rf carrier frequency. Relative to a continuous rf field of equivalent field strength, the use of small flip angle pulses does not reduce the amount of undesirable homonuclear Hartmann-Hahn cross polarization¹⁷. If the pulse spacing is τ_d and the pulse duration is τ_p , the pulsed spin lock increases the average power used

during spin lock by $(\tau_d + \tau_p)/\tau_p$ over a continuous spin lock of the same effective field strength. In some situations, this can lead to undesirable sample heating effects. The $\sin^2 \theta$ signal loss that occurs in the scheme of Figure 3(b) also applies to a series of small flip angle α pulses, and this problem can again be corrected by the application of two 90°_y bracketing pulses (Figure 4d).

5 MINIMIZATION OF J CONTRIBUTIONS

Coherent magnetization transfer, primarily via zero quantum coherence, has been a major nuisance in NOESY spectra, where it gives rise to antiphase cross peaks of zero integrated intensity.^{2,3,27} A similar problem exists in ROESY, where there are actually two distinct mechanisms for coherent transfer of magnetization between J -coupled spins: COSY and HOHAHA.

5.1 COSY Artifacts in ROESY

Considering the simplest 2D scheme of Figure 3(b), the experiment can also be considered as a COSY experiment²⁸ with a very long mixing pulse. During the evolution period t_1 , A-spin magnetization becomes antiphase with respect to its coupling partner, X, and is subsequently transferred by the spin lock pulse, of total flip angle β , into antiphase X spin magnetization. In product operator terms,

$$\begin{aligned} \hat{A}_y &\xrightarrow{t_1} \cos(\pi J_{AX} t_1) \hat{A}_y - 2 \sin(\pi J_{AX} t_1) \hat{A}_x \hat{X}_z \\ &\xrightarrow{\beta_y} +2 \sin^2 \beta \sin(\pi J_{AX} t_1) \hat{A}_z \hat{X}_x + \dots \end{aligned} \quad (11)$$

Even though β varies spatially over the sample owing to rf inhomogeneity, $\sin^2 \beta$ does not average to zero. However, with neither spin A nor X on resonance, the effective rf fields experienced by the two spins, v_{effA} and v_{effX} , will always be stronger than the nominal rf field strength v :

$$\begin{aligned} v_{\text{effA}} &= v \left(1 + \frac{\delta_A^2}{v^2} \right)^{1/2} \approx v + \frac{\delta_A^2}{2v} \\ v_{\text{effX}} &= v \left(1 + \frac{\delta_X^2}{v^2} \right)^{1/2} \approx v + \frac{\delta_X^2}{2v} \end{aligned} \quad (12)$$

where δ_A and δ_X are the offsets of spins A and X. The effective flip angles β_A and β_X experienced by each of the two spins will therefore differ, and the term $\sin^2 \beta$ must be rewritten as $\sin \beta_A \sin \beta_X$, and this product averages to zero when $(\delta_A^2 - \delta_X^2)\tau/2v$ varies rapidly over the sample volume, where τ is the duration of the spin lock period. COSY-type artifacts in ROESY spectra can therefore be minimized by

1. selecting the carrier position judiciously, to maximize $\delta_A^2 - \delta_X^2$,
2. using a relatively weak spin lock field strength v , and
3. using a long mixing time τ .

There are limits on how weak a spin lock field strength can be used, however, since the effective fields of the two locked spins will increasingly tilt out of the transverse plane with decreasing ν . If the effective fields for spins A and B make angles of θ_A and θ_B with the z axis, chosen parallel to the static magnetic field, the cross-relaxation rate becomes:^{10,14}

$$R'_{AB} = \sin \theta_A \sin \theta_B R_{AB} + \cos \theta_A \cos \theta_B R_{AB}^L \quad (13)$$

where R_{AB} and R_{AB}^L are the transverse and longitudinal A–B cross-relaxation rates [cf. equations (6) and (9)]. Quantitative analysis of ROE cross-peak intensities should therefore account for the offsets and θ angles of the two spins involved. For molecules in the slow motion limit, R_{AB}^L and R_{AB} are of opposite sign, and θ values smaller than about 60° will seriously degrade sensitivity. In fact, if the offset and rf field strength are chosen such that the spins are aligned close to the magic angle ($\theta \approx 35^\circ$), the direct cross relaxation R'_{AB} will be zero in the slow tumbling limit, facilitating the study of correlated cross relaxation.^{10–13}

5.2 HOHAHA Artifacts in ROESY

COSY artifacts of the type discussed above are easily recognized, since they yield the characteristic antiphase multiplet pattern with zero integrated intensity. A second type of magnetization transfer can occur among J -coupled spins, and yields in-phase multiplet patterns that are of the same sign as the diagonal resonances, i.e., the artifacts are of opposite sign to the true ROESY cross peaks. This so-called homonuclear Hartmann–Hahn effect (HOHAHA) occurs when the difference in effective spin lock fields, $\nu_A - \nu_B$, is not much larger than the J coupling between A and B. This effect is fully analogous to the heteronuclear Hartmann–Hahn effect, which is commonly used for cross polarization of low- γ nuclei in solids^{29,30} and liquids.^{31,32}

For an isolated A–B spin pair, starting with A-spin magnetization locked along the effective spin lock field, the time dependence of the HOHAHA magnetization transfer, in the absence of an ROE effect, is given by

$$\hat{A}_z \rightarrow (1 + c^2 + s^2 \cos 2qt) \hat{A}_z + s^2(1 - \cos 2qt) \hat{B}_z + \text{antiphase terms} \quad (14a)$$

with

$$\left. \begin{aligned} c &= \cos 2\phi, \quad s = \sin 2\phi, \quad \tan 2\phi = \frac{(1 + \cos \alpha) J_{AB}}{2(\nu_A - \nu_B)} \\ \alpha &= \theta_A - \theta_B \quad 2q = 2\pi[(\nu_A - \nu_B)^2 + \frac{1}{4}(1 + \cos \alpha)^2 J_{AB}^2]^{1/2} \end{aligned} \right\} \quad (14b)$$

In equation (14a), the z axes have been chosen parallel to the effective field directions of the two spins, and $\hat{A}_z$ and $\hat{B}_z$ represent the in-phase A and B spin magnetization components along their respective effective fields. The angle between the two effective fields is α . Equation (14) illustrates the oscillatory behavior of the HOHAHA magnetization transfer as a function of mixing time duration. Provided $|\nu_A - \nu_B| \gg J_{AB}$, the angle 2ϕ becomes very small, resulting in a vanishingly small amount of net magnetization transfer. For reliable ROESY cross-relaxation measurements

involving J -coupled spins, it is therefore essential to ensure Hartmann–Hahn mismatching for J -coupled spin pairs. When the J -coupled spins A and B are very close in chemical shift and adequate Hartmann–Hahn mismatching is not possible because of the constraints imposed by equation (14), cross relaxation between A and a third spin X will also give rise to a spurious Hartmann–Hahn relayed ROESY cross peak between B and X.^{17,33} equation (14), strictly speaking, only applies for an isolated pair of coupled spins. The presence of other protons, coupled to either A or B, has the effect of making the Hartmann–Hahn match condition less sharp, and requires a larger difference $|\nu_A - \nu_B|$ to ensure minimal HOHAHA contributions.¹⁷ In practice, a reasonable compromise between minimizing the Hartmann–Hahn effects and maximizing the transverse cross relaxation is to use a spin lock rf field strength γB_2 that is at least twice as large as the width of the spectral region of interest and to position the carrier frequency on one side of the spectrum, well outside the region of interest, such that the effective field in the center of the spectrum makes an angle of about 70° with the static magnetic field. This results in an effective mismatch $|\nu_A - \nu_B| = 0.34 |\delta_A - \delta_B|$, whereas, according to equation (13), the rate of cross relaxation is reduced by less than about 25 %. To avoid the need to use very large spectral windows and associated large data matrix sizes, the effective position of the rf carrier may be shifted just during the spin lock duration by ‘phase ramping’ the spin lock pulse (Figure 3e,f). For example, if the phase of the spin lock field is increased by 10° every $m \mu\text{s}$, this has the effect of shifting the effective spin lock field by $10/(360m)$ MHz upfield or downfield from its original position.^{10,34}

A detailed description of HOHAHA effects in ROESY has also been presented by Elbayed and Canet.³⁵

5.3 Transverse ROESY With Minimal HOHAHA

Hwang and Shaka³⁶ have proposed an interesting variant of the ROESY experiment that is aimed at minimizing HOHAHA contributions. This experiment, which they refer to as transverse ROESY or T-ROESY, should not be confused with the tilted-frame T-ROESY experiment of Brüschweiler et al.,¹⁰ which is aimed at measuring cross-correlation effects. In the transverse T-ROESY experiment, the mixing period consists of phase-alternated 180° pulses, applied preferably with no time between the pulses (Figure 3g). Near resonance, a $180^\circ_x 180^\circ_{-x}$ pulse pair has the net effect of a $4 \times (90^\circ - \theta)$ rotation about the y axis, where θ is again the angle between the effective field and the field B_0 . Thus, a series of $180^\circ_x 180^\circ_{-x}$ pulse pairs has the net effect of ‘spin locking’ along the y axis with a spin lock field that varies approximately linearly with the resonance offset frequency δ , as $2\delta/\pi$. The strong offset dependence of the Zeeman part of the Hamiltonian minimizes strong coupling effects during the mixing period, and thereby minimizes Hartmann–Hahn effects. The trajectories of the ‘locked’ spins during the mixing period are the same as in a rotary echo $T_{2\rho}$ experiment,³⁷ and the spins, on average, are aligned for equal durations along the y and z axes. As a consequence, the effective cross-relaxation rate $R_{AB}(\text{T-ROESY})$ is the average of the transverse cross-relaxation rate R_{AB} , equation (6), and the longitudinal cross-relaxation rate R_{AB}^L , equation (9). For macromolecules, the opposite signs of R_{AB} and R_{AB}^L result in as much

as a fourfold reduction in cross relaxation rate compared with the standard ROESY experiment, making this type of transverse ROESY experiment less effective. However, for smaller compounds, this disadvantage is less serious, and the reduction in HOHAHA effects frequently outweighs the decrease in cross relaxation rates.³⁸ Mixing schemes that are more elaborate than the above-mentioned $180^\circ_x 180^\circ_{-x}$ pulse pair combination have also been suggested by Hwang and Shaka,³⁶ but, in practice, the simpler sequence appears to yield the most reliable results.

6 EXAMPLES OF ROESY APPLICATIONS

A few practical examples of ROESY applications are discussed below. Figure 5 shows an application of the original 1D CAMELSPIN scheme to a linear tetrasaccharide. The bottom trace is the reference spectrum, obtained after a 90°_x pulse followed by a 250 ms spin lock pulse applied along the y axis. The middle spectrum represents the same experiment, preceded by a selective 180° inversion of the highest frequency (most downfield) anomeric proton at 5.1 ppm. The top spectrum shows the difference, which exhibits significant ROEs between H-1 of one sugar unit and the H-2 and H-3 protons across the interglycosidic linkage, in addition to an intrasidue ROE to its vicinal H-2 proton.

Figure 6 shows the application of the 2D ROESY experiment to a cyclic hexapeptide, recorded at 270 MHz ^1H frequency with the pulse scheme of Figure 3(b). In order to emphasize how serious a problem the HOHAHA may constitute, a strong (5 kHz) spin lock field was used during the mixing period and the carrier was positioned in the center of the aliphatic region, at 3.1 ppm. Only positive contour levels, of the same sign as the diagonal resonances, are shown in this

Figure 5 Spectra recorded with the scheme of Figure 3(a) for a tetrasaccharide. (a) Without selective inversion prior to the 90°_x -SL_y sequence. (b) with selective inversion of the highest frequency (most downfield) anomeric proton. (c) The difference spectrum. Positive resonances in (c) result from ROE interactions. Reprinted from Bothner et al.⁵

figure, and all of these cross peaks are caused by spurious magnetization transfer via the HOHAHA effect. Strong HOHAHA cross peaks are seen between the H^α and methyl protons of both the D- and the L-Ala residues, and among all the proline protons. However, true ROE contributions are also abundant in this spectrum, as illustrated by the two insets, which represent cross sections taken at the diagonal positions of the L-Ala H^N and H^α resonances. The L-Ala H^N resonance, for example, shows ROE interactions with its intrasidue methyl protons, with D-Ala H^N , and with all of the proline protons. By shifting the carrier to a higher frequency position (5.1 ppm) and reducing the strength of the spin lock field to 2 kHz, the HOHAHA contributions are greatly diminished, and only two of the proline protons (H^δ and the H^α shifted most to high frequency) exhibit significant ROEs to L-Ala H^N .¹⁸ ROE interactions to the remaining proline protons are spurious, and are relayed via HOHAHA from Pro H^α and Pro H^δ to the other ring protons.

Figure 7 illustrates the application of ROESY to basic pancreatic trypsin inhibitor, a 58-residue protein. This experiment was carried out in H_2O without solvent presaturation, using a water-flip-back scheme.^{39,40} The figure compares F_1 cross-sections, taken at the F_2 frequency of Tyr-21 H^N , through the 2D ROESY (a) and NOESY (b) spectra. To compensate for the difference in longitudinal and transverse cross-relaxation rates, the NOESY mixing time (120 ms) was twice as long as for the ROESY experiment. Besides a slightly higher signal-to-noise ratio in the NOESY spectrum, the two cross sections exhibit some interesting differences. For example, the cross peak to Phe-45 H^N is relatively weak in the ROESY spectrum compared with the other cross peaks. This is due, in part, to the substantial tilt ($\theta \approx 68^\circ$) of the two spin lock fields [cf. equation (13)], which accounts for a loss of about 20% in the ROE build-up rate. Second, because no 90° bracketing pulses of the type shown in Figure 3(c) were used in this scheme, another loss of about 14% occurs (see above). Another interesting difference is seen for the Arg-20 H^β protons. Both NOESY and ROESY spectra show strong cross relaxation to the highest frequency proton of the two H^β protons, but for the low frequency H^β , the ROE cross peak is opposite in sign to the direct ROE cross peaks, indicating that it results from an indirect interaction, presumably via its geminal proton. Therefore, the NOE cross peak observed for the low frequency Arg-20 H^β proton in Figure 7(b) must also be caused largely by spin diffusion. The same is probably true for the other weak cross peaks observed in the NOESY cross-section, but absent in the ROESY spectrum. Finally, the backbone amide proton of Tyr-21 shows a NOE interaction to Tyr-21 H^δ , with only a very weak cross peak at the adjacent H^ϵ resonance, which is presumably due to spin diffusion. In the ROESY spectrum, the cross peaks to H^δ and H^ϵ are of comparable intensity, however, because the H^δ ROE cross-peak intensity is relayed efficiently to H^ϵ owing to the small H^δ - H^ϵ chemical shift difference and the large H^δ - H^ϵ J coupling.

7 DIFFERENT AREAS OF APPLICATION

7.1 Molecular Structure

Most applications of ROESY published to date deal with determination of either the primary structure, the

Figure 6 270 MHz 2D ROESY spectrum of a cyclic hexapeptide, (D-Ala,L-Pro,L-Ala)₂. Only positive contour levels (for peaks with the same sign as the diagonal) are shown. The spectrum has deliberately been recorded to maximize HOHAHA contributions by positioning the carrier at 3.1 ppm and using a strong rf field strength ($\gamma B_1 = 5$ kHz) during the 200 ms spin lock. All contoured cross peaks are caused by HOHAHA transfer. The two F_1 cross sections, shown as insets, illustrate the presence of ROE cross peaks in this spectrum

stereochemistry, or the conformation of intermediate size molecules that show vanishingly weak laboratory frame NOEs. Because of the generally good ^1H resonance dispersion in peptides, HOHAHA effects are usually not a serious problem, and numerous applications of ROESY to the study of peptide conformation have appeared in the recent literature. Applications to the study of carbohydrate structure are also

widespread, although the lack of resonance dispersion found in this class of molecules requires very careful interpretation to avoid the pitfalls of HOHAHA-relayed false ROE cross peaks. By far the largest number of literature reports on ROESY applications relates to determination of the primary structures and/or absolute configurations of natural products such as alkaloids, carotenoids, antibiotics, and other complex

Figure 7 Comparison of F_1 cross sections through (a) the ROESY and (b) the NOESY spectra of BPTI, taken at the F_2 frequency of the Tyr-21 NH resonance. Both spectra were recorded at 500 MHz ^1H frequency under similar conditions, except for the mixing times (ROESY, 60 ms; NOESY, 120 ms). The ROESY carrier position was at 4.65 ppm and a 6.3 kHz spin lock field was used. From Bax.¹⁷

hydrocarbons. Interesting applications have also been reported for the study of the structure of inclusion complexes and other intermolecular interactions.

7.2 Macromolecular Structure

Bauer et al.⁸ demonstrated by both computer simulation and experiment that spin diffusion effects in DNA generally pose less of a problem in ROESY spectra than in the corresponding NOESY spectra. They demonstrate, for example, that in regular B-form DNA, the ROE cross peak between the base H-6/H-8 proton and the H-1' sugar proton of the preceding nucleotide never reaches a measurable value before it changes sign owing to the indirect three-spin effect via the vicinal H-2'' proton. Although the sequential base-to-H-1' NOE cross peak frequently plays a key role in obtaining the sequential resonance assignments in DNA, the ROE experiment proves that it is almost entirely caused by spin diffusion, even at short mixing times, and it therefore has little value in structure calculations. Because of the absence of long-range NOE constraints in most regular types of DNA and RNA structure, it has been argued that it is essential to determine in a very precise manner the limited number of distances that can be measured, and the ROESY experiment can play an important role in this process.

In proteins, the emphasis has been on determining as many NOE interactions as possible,²¹ and the value of using very precise interproton distances, or upper limits thereof, has not

yet been convincingly demonstrated. Nevertheless, there are numerous situations where the ROESY experiment can provide important distance information in a sensitive manner, which can be critical for stereospecific assignment of H^β methylene protons, for example.⁴¹ In the NOESY spectrum, the H^α protons of residues with a C^β methylene site invariably show NOE cross peaks to both H^β protons. If one of the H^β protons shows a weaker NOE to H^α than does its geminal partner, this could either be caused by the *gauche* and *trans* difference in $\text{H}^\alpha\text{--H}^{\beta 2}$ and $\text{H}^\alpha\text{--H}^{\beta 3}$ distances for a χ_1 rotamer of -60° or 180° , or by a small twist of a $\chi_1 = 60^\circ$ rotamer. In the ROESY spectrum, a *trans* ROE to a H^β methylene is never observed, since this interaction is again dominated by the three-spin effect via the *gauche* H^β proton. If H^α shows positive ROEs to both H^β methylene protons, this indicates a χ_1 torsion angle of $+60^\circ$, provided that HOHAHA relay via the large geminal $^1\text{H}\text{--}^1\text{H}$ J coupling can be excluded.

7.3 Identification of Exchange Processes

As pointed out by Bothner-By et al.⁵ in their original report,⁵ the ROESY experiment is ideally suited for identifying chemical exchange processes that are sufficiently slow to show separate resonances for a single proton, in two or more different chemical environments, but sufficiently fast to measure magnetization transfer. The sign of the cross peak immediately discriminates between cross relaxation and chemical exchange types of magnetization transfer. In proteins and nucleic acids,

cross relaxation and chemical exchange frequently occur on similar timescales, and ROESY spectra have been used extensively to identify a variety of slow exchange processes, such as aromatic ring flipping in proteins,^{42,43} monomer-duplex equilibria in DNA,⁴⁴ and conformational rearrangement in a paramagnetic model heme.⁴⁵

7.4 Protein Hydration

A very important application for distinguishing chemical exchange from cross-correlation effects is found in the study of protein hydration. NOE interactions between labile amide protons in a protein and the bulk water resonance are indistinguishable from hydrogen exchange. In ROESY spectra, these two effects can be conveniently distinguished by the sign of the corresponding cross peak, however.^{6,7} More details are given in *Protein Hydration*

1 INTRODUCTION

The meaning of the expression ‘Overhauser effect’ has considerably evolved over the years, and the breadth of applications could hardly have been foreseen from the original work.¹ The modern sense of the expression can be traced back to the work of Ionel Solomon.² In essence, the Overhauser–Solomon effect is due to a migration of populations between eigenstates which is induced by dipole–dipole interactions that are modulated by rotational diffusion of the molecule, usually in isotropic solution.^{3,4} In today’s terminology, the effect can be rationalized in terms of a partial interconversion of the expectation values of the longitudinal components of angular momentum, e.g. in terms of transformations of the type $\langle I_z^A \rangle \rightsquigarrow \langle I_z^X \rangle$. The rate of this transformation, which is known as the cross-relaxation rate, and which is usually represented in Solomon’s notation by the symbol σ_{AX} , is proportional to the inverse sixth power of the distance r_{AX} between the nuclei A and X. The measurement of σ_{AX} may therefore give very accurate information about the distance r_{AX} . Such measurements are widely used both to study the conformations of small molecules and to investigate the structure of macromolecules such as proteins and nucleic acids, as well as supramolecular assemblies ranging from enzyme/substrate systems to protein/DNA complexes.

2 MEASUREMENT OF CROSS RELAXATION

It might be argued that all methods designed to observe Overhauser effects are by necessity selective. Indeed, if one wishes to monitor a process of the type $\langle I_z^A \rangle \rightsquigarrow \langle I_z^X \rangle$, one must initially perturb thermal equilibrium in a selective manner. If the system were in equilibrium, so that the density operator of a two-spin system would have the form $\sigma^{\text{eq}} = I_z^A + I_z^X$, the flow of Zeeman order from one spin to the other would remain invisible. On the other hand, if one saturates one of the spins, or if one of the spins is inverted (e.g. $\langle I_z^A \rangle \rightarrow -\langle I_z^A \rangle$), either selectively⁵ or in the course of a two-dimensional experiment,^{6–8} it becomes possible to observe the migration of Zeeman order. In a selective one-dimensional experiment, we shall refer to the spin A that is inverted initially as ‘source’ spin. In practice, one normally considers a difference spectrum by subtracting the signals of

a perturbed system from the signals excited by applying a simple monitoring pulse to a system in thermal equilibrium. In the absence of cross relaxation, only the source spin A gives rise to a signal in the difference spectrum. As the system recovers after the initial perturbation during a relaxation or mixing interval τ_m , the signal of the source spin A decreases, while the signal of the ‘target’ spin X builds up if a cross-relaxation process $\langle I_z^A \rangle \rightsquigarrow \langle I_z^X \rangle$ occurs. Ultimately, all signals in the difference spectrum vanish because of longitudinal spin–lattice relaxation.

A very similar behavior is observed in two-dimensional Nuclear Overhauser Effect Spectroscopy (NOESY).^{6–8} The τ_m -dependence of the amplitude of a diagonal peak a_{AA} centered at $\omega_1 = \omega_2 = \Omega_A$ is the same as the τ_m dependence of the signal of the source spin A in a one-dimensional difference spectrum. Likewise, the build-up of a cross peak a_{AX} centered at $\omega_1 = \Omega_A$ and $\omega_2 = \Omega_X$ follows the same pattern as the τ_m -dependence of the signal of a target spin X in a difference spectrum. This analogy is by no means fortuitous, for it may be argued that the two-dimensional NOESY method is equivalent to a series of one-dimensional experiments employing selective inversion at the frequencies of different source spins. The main difference lies in the fact that selective pulses required to invert the source magnetization I_z^A have a finite duration, so that one may have to consider cross-relaxation effects that build up *during* these selective pulses. By contrast, the nonequilibrium I_z^A components that begin their migration at the beginning of the mixing time τ_m of a two-dimensional NOESY experiment are created almost instantaneously, typically within the length of a nonselective 90° pulse. It is this feature which makes the nonselective, two-dimensional form of NOESY so attractive for studying systems with broad lines, such as macromolecules in isotropic solution or crystalline and amorphous powders. Yet if the linewidths are sufficiently narrow to make selective manipulations possible, i.e. if inhomogeneous broadening is not too pronounced and if the transverse relaxation time T_2 is not too short compared with the duration of selective pulses, one may gain in efficiency and speed by resorting to selective one-dimensional variants of NOESY. The relative merits depend on the situation: if the spectra are very crowded, it may be necessary to invert very narrow regions which would require very long pulses (typically about 100 ms to invert a region of about 30 Hz by a Gaussian Q^3 cascade⁹). In macromolecules, one would expect severe losses of magnetization due to T_2 relaxation during such long pulses, and one would have to consider the build up of cross-relaxation effects during such pulses. If, on the other hand, the spectral dispersion is sufficient, as one might expect at high fields for molecules of medium size (say, proteins with about 60 residues), it is not necessary to be too selective, and one might use for example a Gaussian Q^3 cascade of 10 ms to invert a region of 300 Hz (0.5 ppm at 600 MHz). Under such conditions, the signal intensities in selective experiments would not suffer too much from T_2 relaxation, cross relaxation during the pulses can be safely neglected, and, in terms of the information obtained per unit time, selective variants of NOESY will tend to be more efficient than nonselective two-dimensional NOESY experiments.

3 QUENCHING OF SPIN DIFFUSION

Since a review of all methods would clearly be beyond the scope of this article, we shall narrow down the definition of ‘selective NOESY’ to a particular class of experiments, where one focuses attention on cross relaxation processes involving two selected source and target nuclei A and X that belong to a larger network which comprises a number of perturbing spins K, K', ... (sometimes referred to as ‘clandestine’ spins). Selectivity is required in the sense that these perturbing spins should not be allowed to participate in cross relaxation. A variety of methods are in development at the time of writing, and it would be premature to make a judgment as to their relative merits.

The simplest approach to this problem¹⁰ consists of *decoupling* all perturbing spins K, K', ... by continuous irradiation or saturation during the τ_m interval in which the migration $\langle I_z^A \rangle \rightsquigarrow \langle I_z^X \rangle$ is allowed to occur. Decoupling implies that two-step spin diffusion processes via perturbing spins K, such as $\langle I_z^A \rangle \rightsquigarrow \langle I_z^K \rangle \rightsquigarrow \langle I_z^X \rangle$, are effectively suppressed.¹⁰ On the other hand, steady-state Overhauser effects will be induced by irradiating K, and these may lead to an enhancement (or to an attenuation, depending on the correlation time τ_c) of the Zeeman polarization of the source and target spins A and X, and this may render the interpretation of the conversion $\langle I_z^A \rangle \rightsquigarrow \langle I_z^X \rangle$ difficult. A more sophisticated approach uses a selective inversion of the magnetization of the perturbing spin $\langle I_z^K \rangle \rightarrow -\langle I_z^K \rangle$ in the middle of the relaxation or mixing interval τ_m . This may be referred to as ‘editing’ of the relaxation matrix.^{11,12} This approach is quite effective provided that the resonance frequency of spin K is known, but is difficult to generalize¹³ to systems containing several perturbing spins K, K', ...

In nonselective two-dimensional experiments, second-order spin-diffusion effects can be identified as such by comparing cross-peak amplitudes in NOESY and in ROESY,¹⁴ since the cross-relaxation rates in the rotating (rot) frame are opposite in sign and are twice as large as those observed in the laboratory (lab) frame ($\sigma_{AX}^{\text{rot}} = -2\sigma_{AX}^{\text{lab}}$). By combining suitable intervals of laboratory and rotating frame cross relaxation in one and the same experiment, it is possible to cancel out cross relaxation altogether.¹⁵ It can be reintroduced by semiselective inversion of a selected group of spins, so that one can measure cross relaxation between spins belonging to this group and all other spins in the neighborhood.¹⁶

It is perhaps easier to focus on cross-relaxation processes between two selected spins A and X in one-dimensional spectroscopy. In the so-called synchronous nutation method,^{17,18} the magnetization vectors of the two spins of interest are forced to nutate about two weak radiofrequency fields applied at the two chemical shifts. Rotary echoes are used to combat the effects of radiofrequency inhomogeneity. The rates of the decay of the magnetization depend on the initial conditions, i.e. in macromolecules the decay rate is faster if the initial density operator is of the form $\hat{\sigma}(0) = \hat{I}_z^A + \hat{I}_z^X$ than if one starts with $\hat{\sigma}(0) = \hat{I}_z^A - \hat{I}_z^X$. The difference of the decay rates allows one to determine the cross-relaxation rate σ_{AX} . In practice, synchronous nutation experiments tend to be rather demanding from an instrumental point of view, and suffer from complications in the presence of scalar couplings.¹⁸

A less demanding one-dimensional experiment has become known under the acronym QUIET-NOESY, which stands for

Figure 1 Sequence for the measurement of transient Overhauser effects with suppression of spin diffusion (QUIET-NOESY). The longitudinal magnetization of a selected source spin A is inverted by a Q^3 Gaussian cascade. In the middle of the relaxation or mixing interval τ_m , both the source spin A and the target spin X are inverted by an audio-modulated Q^3 Gaussian cascade. At the end of the τ_m interval, the longitudinal component $\langle I_z^X \rangle$ is converted into transverse $\langle I_x^X \rangle$ magnetization by a 270° Gaussian G^1 pulse, and transferred for observation to a scalar coupled partner $\langle I_x^X \rangle \rightarrow \langle I_x^M \rangle$ through a homonuclear Hartmann–Hahn effect during a doubly selective irradiation period τ_{DSI} . A difference spectrum is obtained by subtracting a signal recorded without initial inversion of the A spin. (Reproduced by permission of the American Chemical Society from Zwahlen et al.¹⁹)

quenching undesirable indirect external trouble in nuclear Overhauser effect spectroscopy,¹⁹ and which allows one to measure the time dependence of selected transient Overhauser effects without being affected by spin diffusion. The sequence shown in Figure 1 bears analogies to QUICK-NOESY (quantitative unravelling of intensities for corroborating knowledge in nuclear Overhauser effect spectroscopy).²⁰ The sequence begins with the inversion of the longitudinal magnetization, $\langle I_z^A \rangle \rightarrow -\langle I_z^A \rangle$, of a selected source spin A. The initial inversion is omitted in complementary experiments, so that the signals can be subtracted in the manner of difference spectroscopy. The longitudinal magnetization (or, more accurately, its deviation from thermal equilibrium) is allowed to migrate freely under the effect of cross relaxation during the first half of the mixing interval τ_m . In the middle of this relaxation time, a fraction of the magnetization has migrated from the spin A, not only to a target spin, $\langle I_z^A \rangle \rightsquigarrow \langle I_z^X \rangle$, but also to various other clandestine spins, $\langle I_z^A \rangle \rightsquigarrow \langle I_z^K \rangle$, $\langle I_z^A \rangle \rightsquigarrow \langle I_z^{K'} \rangle$, ... , in as far as the cross-relaxation rates σ_{AK} , $\sigma_{AK'}$, ... do not vanish. The longitudinal magnetization components of both source and target spins are then inverted simultaneously, $\langle I_z^A \rangle \rightarrow -\langle I_z^A \rangle$ and $\langle I_z^X \rangle \rightarrow -\langle I_z^X \rangle$. This can be achieved by an audiomodulated Q^3 Gaussian cascade.²¹ The $\langle I_z^X \rangle$ component that remains at the end of the τ_m interval is almost entirely due to the direct conversion $\langle I_z^A \rangle \rightsquigarrow \langle I_z^X \rangle$, and not to spin diffusion. In principle, it should be possible to observe this $\langle I_z^X \rangle$ magnetization directly, but in practice we convert the longitudinal component $\langle I_z^X \rangle$ into $\langle I_x^X \rangle$ by a selective 270° Gaussian G^1 pulse.²² The coherence $\langle I_x^X \rangle$ is then transferred to a scalar-coupled ‘spy’ nucleus, $\langle I_x^X \rangle \rightarrow \langle I_x^M \rangle$, through a homonuclear Hartmann–Hahn effect^{23,24} during a doubly selective irradiation (DSI) period t_{DSI} .

The mechanism of the experiment of Figure 1 may be explained by simulating the time dependence of the relevant expectation values of a system with three spins A, K, and X, as in Figure 2. The population dynamics are governed by the

Figure 2 Simulations of the time dependence of the polarizations $\langle I_z^A \rangle$, $\langle I_z^K \rangle$, and $\langle I_z^X \rangle$ in the course of the relaxation interval τ_m when $\langle I_z^A \rangle$ and $\langle I_z^K \rangle$ are inverted in the middle. The parameters of the relaxation matrix are given in the text. Note the buildup of both $\langle I_z^K \rangle$ and $\langle I_z^X \rangle$ in the first half of τ_m , which is followed by a decay in the second half of τ_m . (Reproduced by permission of the American Chemical Society from Zwahlen et al.¹⁹)

master equation:

$$\frac{d}{dt} \begin{pmatrix} \langle I_z^A \rangle \\ \langle I_z^K \rangle \\ \langle I_z^X \rangle \end{pmatrix} = - \begin{pmatrix} \rho_A & \sigma_{AK} & \sigma_{AX} \\ \sigma_{AK} & \rho_K & \sigma_{KX} \\ \sigma_{AX} & \sigma_{KX} & \rho_X \end{pmatrix} \begin{pmatrix} \langle I_z^A \rangle - \langle I_z^A \rangle_{eq} \\ \langle I_z^K \rangle - \langle I_z^K \rangle_{eq} \\ \langle I_z^X \rangle - \langle I_z^X \rangle_{eq} \end{pmatrix} \quad (1)$$

Since the signals are obtained from the difference between two experiments, the equilibrium terms in this equation may be dropped.

Figure 2 shows the time dependence of $\langle I_z^A \rangle$, $\langle I_z^K \rangle$, and $\langle I_z^X \rangle$ as a function of time within a mixing interval of fixed duration $\tau_m = 0.5$ s. We have chosen $\rho_A = \rho_X = 3.02 \text{ s}^{-1}$, $\rho_K = 5 \text{ s}^{-1}$, $\sigma_{AK} = \sigma_{KX} = -1 \text{ s}^{-1}$, and $\sigma_{AX} = -0.02 \text{ s}^{-1}$. This is consistent with a system where $r_{AK} = r_{KX} < r_{AX}$ with dipolar relaxation in the slow tumbling limit (where $\rho_i = -\sum_j \sigma_{ij}$), with additional contributions to the diagonal elements due to chemical shift anisotropy and external random fields. In the first half of the τ_m period, one observes a typical (triexponential) decay of $\langle I_z^A \rangle$, which corresponds to the τ_m -dependence of the diagonal peak amplitude in NOESY. Besides the rapid buildup of $\langle I_z^K \rangle$ in Figure 2(b), one observes a much slower buildup of $\langle I_z^X \rangle$ which is mostly due to a two-step process in this example, since $\sigma_{AX}\tau_m$ is much smaller than $\frac{1}{2}\sigma_{AK}\sigma_{KX}\tau_m^2$. In the middle of the mixing period in Figure 2, the signs of $\langle I_z^A \rangle$ and $\langle I_z^X \rangle$ are reversed, while $\langle I_z^K \rangle$ remains unaffected. For clarity, this sign reversal is assumed to occur instantaneously, although in practice the audiomodulated Q^3 cascade must have a finite duration. In the second half of the mixing period, the $\langle I_z^K \rangle$ term decays: instead of receiving more polarization from the $\langle I_z^A \rangle$ bath, $\langle I_z^K \rangle$ now loses part of its order because the flow occurs in the reverse direction. The magnitude of the $\langle I_z^X \rangle$ term (deviation from zero) also decays,

again because the flow of polarization, which went from K to X in the first half of τ_m , is reversed in the second half. At the end of τ_m , the polarization $\langle I_z^X \rangle$ that remains is mostly due to the direct transfer $A \rightsquigarrow X$ and not to the two-step process $A \rightsquigarrow K \rightsquigarrow X$.

Figure 3 shows an application to the self-complementary palindromic DNA dodecamer d(CGCGAATTCGCG)₂ (where d = deoxy, C = cytidine, G = guanosine, A = adenosine, and T = thymine) known as ‘Dickerson’s dodecamer’.^{25,26} Figures 3(a) and 3(c) were recorded with the QUICK-NOESY scheme,²⁰ i.e. without quenching spin diffusion, and show cross-relaxation processes from two deoxyribose protons H-2’ and H-2’’ of the cytosine-9 residue to the aromatic H-6 proton of the same residue. Figures 3(b) and 3(d) show the results obtained using the QUIET-NOESY sequence of Figure 1 to quench spin diffusion. Note that the C9–H-2’ $\rightsquigarrow$ C9–H-6 transfer is not dramatically affected by the quenching process, whereas the C9–H-2’’ $\rightsquigarrow$ C9–H-6 transfer is almost entirely eliminated. This proves at a glance that the former process

Figure 3 Selective measurements of transient Overhauser effects in the duplex d(CGCGAATTCGCG)₂ in D₂O at 303 K. (a) and (b): Cross relaxation from the cytosine-9 deoxyribose proton C9–H-2’ to the aromatic proton C9–H-6. (c) and (d): Cross relaxation from C9–H-2’’ to C9–H-6. The magnetization was transferred from the target spin C9–H-6 to the spy spin C9–H-5 through a homonuclear Hartmann–Hahn effect. (a) and (c): Buildup curves obtained with spin diffusion, recorded with the QUICK-NOESY method (i.e. by dropping the modulated Q^3 cascade from the sequence of Figure 1). (b) and (d): Buildup curves obtained without spin diffusion, i.e. with the QUIET-NOESY method of Figure 1. (Reproduced by permission of the American Chemical Society from Zwahlen et al.¹⁹)

corresponds to a 'true' Overhauser effect, while the latter merely results from spin diffusion. In the latter case, it appears that the C9–H-2' proton acts as clandestine K proton that relays the information, i.e. the overall pathway would be H-2'' $\rightsquigarrow$ H-2' $\rightsquigarrow$ H-6.

Selective NOESY schemes such as the experiment of Figure 1 allow one to obtain more accurate measurements of cross-relaxation rates σ_{AX} , and hence more reliable estimates of internuclear distances r_{AX} .

1 WHY ARE THREE- (3D) AND FOUR-DIMENSIONAL (4D) EXPERIMENTS REQUIRED?

The principal source of geometric information used to solve 3D structures of macromolecules by NMR resides in short ($<5\text{ \AA}$), approximate, interproton distance restraints derived from nuclear Overhauser enhancement (NOE) measurements.^{1–7} In order to extract this information it is essential first to completely assign the ^1H spectrum of the macromolecule in question and then to assign as many structurally useful NOE interactions as possible. The larger the number of NOE restraints, the higher the precision and accuracy of the resulting structures.^{7–9} Indeed, with current state-of-the-art methodology it is now possible to obtain NMR structures of proteins at a precision and accuracy comparable to $2\text{ \AA}$ resolution crystal structures.^{8–12}

For proteins of 100 residues or less, conventional homonuclear two-dimensional (2D) NMR methods can be applied with a considerable degree of success.^{1–7,13,14} As the number of residues and molecular weight increases beyond 100 kDa and 12 kDa, respectively, two main obstacles present themselves, which has made it necessary to extend the 2D NMR techniques to higher dimensions and to develop new approaches. First, the increased spectral complexity arising from the presence of a larger number of protons results in extensive chemical shift overlap and degeneracy, rendering the 2D spectra uninterpretable. Second, the rotational correlation time increases with molecular weight resulting in large ^1H linewidths and a concomitant severe decrease in the sensitivity of correlation experiments based on intrinsically small three-bond ^1H – ^1H couplings. These obstacles can be overcome by increasing the dimensionality of the spectra to resolve problems associated with spectral overlap and by simultaneously making use of heteronuclear couplings that are larger than the linewidths to circumvent limitations in sensitivity.^{8,9} This approach

necessitates uniform ^{15}N and/or ^{13}C labeling of the macromolecule under consideration.

The concept of increasing spectral dimensionality to extract information can perhaps most easily be understood by analogy.⁸ Consider for example this Encyclopedia. In a one-dimensional (1D) representation, all the information (i.e. words and sentences arranged in a particular set order) present in the Encyclopedia would be condensed into a single line. If this line were expanded to two dimensions in the form of a page, the odd word may be resolved but the vast majority would still be superimposed on each other. When this page is expanded into a book (i.e. three dimensions) comprising a set number of lines and words per page, as well as a fixed number of pages, some pages may become intelligible, but many words will still lie on top of each other. The final expansion to the multivolume book (i.e. four dimensions) then makes it possible to extract in full all the information present in the individual entries of the encyclopedia.

2 THE DESIGN AND IMPLEMENTATION OF 3D AND 4D EXPERIMENTS

The design and implementation of higher dimensionality NMR experiments can be carried out by the appropriate combination of 2D NMR experiments, as illustrated schematically in Figure 1. A 3D experiment is constructed from two 2D pulse schemes by leaving out the detection period of the first experiment and the preparation pulse of the second.¹⁵ This results in a pulse train comprising two independently incremented evolution periods t_1 and t_2 , two corresponding mixing periods M_1 and M_2 , and a detection period t_3 . Similarly, a 4D experiment is obtained by combining three 2D experiments in an analogous fashion. Thus, conceptually n -dimensional NMR can be conceived as a straightforward extension of 2D NMR. The real challenge, however, of 3D and 4D NMR is twofold: first, to ascertain which 2D experiments should be combined to best advantage; and second, to design the pulse sequences in such a way that undesired artifacts, which may severely interfere with the interpretation of the spectra, are removed. This task is far from trivial.

Heteronuclear 3D and 4D NMR experiments exploit a series of large one-bond heteronuclear couplings for magnetization transfer through bonds which are summarized in Figure 2. This, together with the fact that the ^1H nucleus is always detected, renders these experiments very sensitive. Indeed, high-quality 3D and 4D heteronuclear-edited spectra can easily be obtained on samples of 1–2 mM uniformly labeled protein in a timeframe that is limited solely by the number of increments that have to be collected for appropriate digitization and the number of phase cycling steps that have to be used to reduce artifacts to an acceptably low level. Typical measurement times are 1–3 days for 3D experiments and 2.5–5 days for 4D ones. A detailed technical review of heteronuclear multidimensional NMR has been provided by Clore and Gronenborn.¹⁶

3 HETERONUCLEAR EDITING OF ^1H – ^1H EXPERIMENTS

Many of the 3D and 4D experiments are based on heteronuclear editing of ^1H – ^1H experiments so that the general

Note how 3D and 4D experiments are constructed by the appropriate linear combination of 2D ones. Abbreviations: P, preparation; E, evolution; M, mixing; and D, detection. In 3D and 4D NMR, the evolution periods are incremented independently

Figure 2 Summary of the one-bond heteronuclear couplings along the polypeptide chain utilized in 3D and 4D NMR experiments

appearance of conventional 2D experiments is preserved and the total number of cross peaks present is the same as that in the 2D equivalents.^{8,9,16–24} The progression from a 2D spectrum to 3D and 4D heteronuclear-edited spectra is depicted schematically in Figure 3. Consider, for example the cross peaks involving a particular ^1H frequency in a 2D NOESY spectrum, a 3D ^{15}N or ^{13}C -edited NOESY spectrum, and finally a 4D $^{15}\text{N}/^{13}\text{C}$ or $^{13}\text{C}/^{13}\text{C}$ -edited NOESY spectrum. In the 2D spectrum a series of cross peaks will be seen from the originating proton frequencies in the F_1 dimension to the single destination ^1H frequency along the F_2 dimension. From the 2D experiment it is impossible to ascertain whether these NOEs involve only a single destination proton or several destination protons with identical chemical shifts. By spreading the spectrum into a third dimension according to the chemical shift of the heteronucleus attached to the destination proton(s), NOEs involving different destination protons will appear in distinct ^1H – ^1H planes of the 3D spectrum. Thus each interaction is simultaneously labeled by three chemical shift coordinates along three orthogonal axes of the spectrum. The projection of all these planes onto a single plane yields the corresponding 2D spectrum. For the purposes of sequential assignment, heteronuclear-edited 3D spectra are often sufficient for analysis. However, when the goal of the analysis is to assign NOEs between protons far apart in the sequence, a 3D ^{15}N - or ^{13}C -edited NOESY spectrum will often prove inadequate. This is because the originating protons are only specified by their ^1H chemical shifts, and more often than not, there are several protons that resonate at the same frequencies. For example, in the case of the 153-residue protein interleukin- 1β , there are about 60 protons that resonate in a 0.4 ppm interval between 0.8 and 1.2 ppm. Such ambiguities can then be resolved by spreading out the 3D spectrum still further into a fourth dimension according to the chemical shift of the heteronucleus attached to the originating protons, so that each NOE interaction is simultaneously labeled by four chemical shift coordinates along four orthogonal axes, namely those of the originating and destination protons and those

of the corresponding heteronuclei directly bonded to these protons.^{25–27} The result is a 4D spectrum in which each plane of the 3D spectrum constitutes a cube in the 4D spectrum.

4 COMPARISON OF 2D, 3D, AND 4D EXPERIMENTS

For illustration purposes it is also useful to compare the type of information that can be extracted from a very simple system using 2D, 3D, and 4D NMR. Consider a molecule with only two NH and two aliphatic protons in which only one NH proton is close to an aliphatic proton. In addition, the chemical shifts of the NH protons are degenerate, as are those of the aliphatic protons, so that only two resonances are seen in the 1D spectrum. In the 2D NOESY spectrum, an NOE will be observed between the resonance position of the NH protons and the resonance position of the aliphatic protons, but it will be impossible to ascertain which one of the four possible NH–aliphatic-proton combinations gives rise to the NOE. By spreading the spectrum into a third dimension, for example by the chemical shift of the ^{15}N atoms attached to the NH protons, the number of possibilities will be reduced to two, provided, of course, that the chemical shifts of the two nitrogen atoms are different. Finally, when the fourth dimension corresponding to the chemical shift of the ^{13}C atoms attached to the aliphatic protons is introduced, a unique assignment of the NH–aliphatic-proton pair giving rise to the NOE can be made.

Figure 4(a) presents a portion of the 2D ^{15}N -edited NOESY spectrum of interleukin- 1β (153 residues) illustrating NOE interactions between the NH protons along the F_2 axis and the C- α ,H protons along the F_1 dimension.¹⁹ Despite the fact that a large number of cross peaks can be resolved, it can be seen that many of the cross peaks have identical chemical shifts in one or other dimensions. For example, there are 15 cross peaks involving NH protons at an $F_2(^1\text{H})$ chemical shift of ~ 9.2 ppm. A single $^1\text{H}(F_1)$ – $^1\text{H}(F_3)$ plane of the 3D ^{15}N -edited NOESY spectrum of interleukin- 1β at $\delta^{15}\text{N}(F_2) = 123.7$ ppm is shown in Figure 4(b). Not only is the number of cross peaks in this slice small, but also at $\delta^1\text{H}(F_3) \sim 9.2$ ppm there is only a single cross peak involving one NH proton. The correlations observed in the ^{15}N -edited NOESY spectrum are through-space ones. Intraresidue correlations from the NH protons to the C- α ,H and C- β ,H protons can similarly be resolved using a 3D ^{15}N -edited HOHAHA spectrum in which efficient isotropic mixing sequences are used to transfer magnetization between protons via three-bond ^1H – ^1H couplings.

The 3D ^{15}N -edited NOESY and HOHAHA spectra constitute only one of several versions of a 3D heteronuclear-edited

Figure 3 Schematic illustration of the progression and relationship between 2D, 3D, and 4D heteronuclear NMR experiments. The solid circles represent NOE cross peaks. In the example shown there are 11 NOEs originating from 11 different protons in the F_1 dimension to a single-frequency position in the F_2 dimension. In the 2D spectrum, it is impossible to ascertain whether there is only one destination proton or several in the F_2 dimension. By spreading the spectrum into a third dimension (labeled F_2), according to the chemical shift of the heteronucleus attached to the destination proton, it can be seen that the NOEs now lie in three distinct $^1\text{H}(F_1)$ – $^1\text{H}(F_3)$ planes, indicating that three different destination protons are involved. However, the ^1H chemical shifts still provide the only means of identifying the originating protons. Hence the problem of spectral overlap still prevents the unambiguous assignment of these NOEs. By extending the spectrum to 4D, each NOE interaction is labeled by four chemical shifts along four orthogonal axes. Thus, the NOEs in each plane of the 3D spectrum are now spread over a cube in the 4D spectrum according to the chemical shift of the heteronucleus directly attached to the originating protons. (Reproduced by permission from Kay et al.²⁵)

spectrum. Many alternative through-bond pathways can be utilized to great effect. Consider, for example, the delineation of amino acid spin systems which involves grouping those resonances which belong to the same residue. In 2D NMR, correlation experiments are used to delineate either direct or relayed connectivities via small three-bond ^1H – ^1H couplings. Even for proteins of 50–60 residues, it can be difficult to delineate long-chain amino acids such as lysine (Lys) and arginine (Arg) in this manner. In heteronuclear 3D NMR an alternative pathway can be employed which involves transferring magnetization first from a proton to its directly attached carbon atom via the large $^1J(\text{C,H})$ coupling (~ 130 Hz), followed by either direct or relayed transfer of magnetization along the carbon

chain via the $^1J(\text{C,C})$ couplings (~ 30 – 40 Hz), before transferring the magnetization back to protons.^{28,29,38} An example of such a spectrum is the so-called HCCH-TOCSY shown in Figure 4(c). The $^1\text{H}(F_1)$ – $^1\text{H}(F_3)$ plane at $\delta^{13}\text{C}(F_2) = 59$ ppm illustrates both direct and relayed connectivities along various side chains originating from C- α ,H protons. As expected, the resolution of the spectrum is excellent and there is no spectral overlap. Just as importantly, however, the sensitivity of the experiment is extremely high and complete spin systems are readily identified in interleukin- 1β even for long side chains, such as those of two Lys residues shown in the Figure. Indeed, analyzing spectra of this kind, it was possible

Figure 4 Example of 2D and 3D spectra of interleukin-1 β recorded at 600 MHz.^{19,30,48,49} The 2D spectrum in (a) shows the NH(F_2 axis)–C- α ,H(F_1 axis) region of a 2D ^{15}N -edited NOESY spectrum. The same region of a single NH(F_3)– ^1H (F_1) plane of the 3D ^{15}N -edited NOESY at $\delta^{15}\text{N}(F_2) = 123.7 \text{ ppm}$ is shown in (b). The actual 3D spectrum comprises 64 such planes and projection of these on a single plane would yield the same spectrum as in (a). Part (c) shows a single $^1\text{H}(F_3)$ – $^1\text{H}(F_1)$ plane of the 3D HCCH-TOCSY spectrum at $\delta^{13}\text{C}(F_2) = 38.3 \pm n\text{SW}$ (where SW is the spectral width of 20.71 ppm in the ^{13}C dimension) illustrating both direct and relayed connectivities originating from the C- α ,H protons. Note how easy it is to delineate complete spin systems of long side chains such as Lys (i.e. cross peaks to the C- β ,H, C- γ ,H, C- δ ,H, and C- ϵ ,H protons are observed) owing to the fact that magnetization along the side chain is transferred via large $^1J(\text{C},\text{C})$ couplings. Several features of the HCCH-TOCSY spectrum should be pointed out. First, extensive folding is employed which does not obscure analysis as ^{13}C chemical shifts for different carbon types are located in characteristic regions of the ^{13}C spectrum with little overlap. Second, the spectrum is edited according to the chemical shift of the heteronucleus attached to the originating proton rather than the destination one. Third, multiple cross checks on the assignments are readily made by looking for the symmetry-related peaks in the planes corresponding to the ^{13}C chemical shifts of the destination protons in the original slice

to obtain complete ^1H and ^{13}C assignments for the side chains of interleukin-1 β .³⁰

Three-dimensional NMR also permits one to devise experiments for sequential assignment which are based solely on through-bond connectivities via heteronuclear

couplings^{16,31,32} and thus do not rely on the NOESY experiment. This becomes increasingly important for larger proteins, as the types of connectivities observed in these correlation experiments are entirely predictable, whereas in the NOESY spectrum, which relies solely on close proximity of protons, it

Figure 5

may be possible to confuse sequential connectivities with long-range ones. These 3D heteronuclear correlation experiments are of the triple resonance variety and make use of one-bond $^{13}\text{CO}(i-1)-^{15}\text{N}(i)$, $^{15}\text{N}(i)-^{13}\text{C}-\alpha(i)$, $^{13}\text{C}(i)-^{13}\text{C}(i)$, and $^{13}\text{C}-\alpha(i)-^{13}\text{CO}(i)$ couplings, as well as two-bond $^{13}\text{C}-\alpha(i-1)-^{15}\text{N}(i)$ couplings. In this manner multiple, independent pathways for linking the resonances of one residue with those of its adjacent neighbor are available, thereby avoiding ambiguities in the sequential assignment (see Table 1).

In practice, only a limited number of 3D triple and double resonance experiments need to be performed to obtain complete assignments. In our experience, the following eight 3D

experiments not only provide all the information required, but are also characterized by high sensitivity and can be recorded in as little as 2 weeks of measuring time. Specifically, the 3D CBCA(CO)NH and HBHA(CBCACO)NH experiments^{33,34} are used to correlate the chemical shifts of C- α /C- $\beta(i-1)$ and H- α /H- $\beta(i-1)$, respectively, of residue $i-1$ with the $^{15}\text{N}(i)/\text{NH}(i)$ chemical shifts of residue i ; and the complementary 3D C(CO)NH and H(CCO)NH experiments³⁵ are used to correlate the chemical shifts of the aliphatic side chain ^{13}C and ^1H resonances, respectively, of residue $i-1$ with the $^{15}\text{N}(i)/\text{NH}(i)$ chemical shifts of residue i . In the first two experiments, magnetization originating on C- β is transferred

Figure 5 Comparison of 2D and 4D NMR spectra of interleukin-1 β recorded at 600 MHz.²⁶ The region between 1 and 2 ppm of the 2D NOESY spectrum is shown in (a). $^1\text{H}(F_2)$ – $^1\text{H}(F_4)$ planes at several $^{13}\text{C}(F_1)$ and $^{13}\text{C}(F_3)$ frequencies of the 4D $^{13}\text{C}/^{13}\text{C}$ NOESY spectrum are shown in (b) to (d). No individual cross peaks can be observed in the 2D spectrum and the letter X has ^1H coordinates of 1.39 and 1.67 ppm. In contrast, only two cross peaks are observed in the boxed region in (b) between 1 and 2 ppm, one of which (indicated by an arrow) has the same ^1H coordinates as the letter X. Further analysis of the complete 4D spectrum reveals the presence of seven NOE cross peaks superimposed at the ^1H coordinates of the letter X. This can be ascertained by looking at the $^{13}\text{C}(F_1)$ – $^{13}\text{C}(F_3)$ plane taken at the ^1H coordinates of X. True diagonal peaks corresponding to magnetization that has not been transferred from one proton to another, as well as intense NOE peaks involving protons attached to the same carbon atom (i.e. methylene protons), appear in only a single $^1\text{H}(F_2)$ – $^1\text{H}(F_4)$ plane of each $^{13}\text{C}(F_1)$, $^1\text{H}(F_2)$, $^1\text{H}(F_4)$ cube at the carbon frequency where the originating and destination carbon atoms coincide (i.e. at $F_1 = F_3$). Thus, these intense resonances no longer obscure NOEs between protons with similar or degenerate chemical shifts. Two examples of such NOEs can be seen in (c), between the C- α ,H protons of Pro-91 and Tyr-90, and (d), between one of the C- β ,H protons of Phe-77 and the methyl protons of Met-95. These various planes of the 4D spectrum also illustrate another key aspect of 3D and 4D NMR, namely the importance of designing the pulse scheme optimally to remove undesired artifacts which may severely interfere with the interpretation of the spectra. Thus, while the 4D $^{13}\text{C}/^{13}\text{C}$ -edited NOESY experiment is conceptually analogous to that of a 4D $^{13}\text{C}/^{15}\text{N}$ -edited one, the design of a suitable pulse scheme is actually much more complex in the $^{13}\text{C}/^{13}\text{C}$ case. This is due to the fact that there are a large number of spurious magnetization transfer pathways that can lead to observable signals in the homonuclear $^{13}\text{C}/^{13}\text{C}$ case. For example, in the 4D $^{15}\text{N}/^{13}\text{C}$ -edited case there are no ‘diagonal peaks’ which would correspond to magnetization that has not been transferred from one hydrogen atom to one another, as the double heteronuclear filtering (i.e. ^{13}C and ^{15}N) is extremely efficient at completely removing these normally very intense and uninformative resonances. Such a double filter is not available in the $^{13}\text{C}/^{13}\text{C}$ case so that both additional pulses and phase cycling are required to suppress magnetization transfer through these pathways. This task is far from trivial as the number of phase cycling steps in 4D experiments is severely limited by the need to keep the measurement time down to practical levels (i.e. less than 1 week). The most efficient way of obtaining artifact-free spectra is through the incorporation of pulse field gradients to suppress undesired coherence transfer pathways.⁵⁰ Indeed, inclusion of six pulse field gradients into the original pulse scheme of Clore et al.²⁶ reduces the phase cycle from eight to two steps.⁵¹ The results of such care in pulse design can be clearly appreciated from the artifact-free planes shown in (b)–(d). However, when a 4D $^{13}\text{C}/^{13}\text{C}$ -edited NOESY spectrum is recorded with the same pulse scheme as that used in the 4D $^{15}\text{N}/^{13}\text{C}$ experiment (with the obvious replacement of ^{15}N pulses by ^{13}C pulses), a large number of spurious peaks are observed along a pseudodiagonal at $\delta^1\text{H}(F_2) = \delta^1\text{H}(F_4)$ in planes where the carbon frequencies of the originating and destination protons do not coincide. As a result, it becomes virtually impossible under these circumstances to distinguish artifacts from NOEs between protons with the same ^1H chemical shifts, as was possible with complete confidence in (c) and (d)

to C- α by a COSY mixing pulse, while in the second pair of experiments, magnetization is transferred from a side-chain C atom along the carbon chain to C- α via isotropic mixing. Intrareidue correlations to the NH group can be obtained from the 3D CBCANH³⁶ and ^{15}N -edited HOHAHA³⁷ experiments. The 3D CBCANH experiment correlates the chemical shifts of C- $\alpha(i)$ /C- $\beta(i)$ [as well as those of C- $\alpha(i-1)$ /C- $\beta(i-1)$], which invariably give rise to weaker cross peaks], with the $^{15}\text{N}(i)$ /NH(i) chemical shifts of residue i ; the 3D ^{15}N -separated HOHAHA experiment correlates the chemical shifts of the side-chain protons of residue i with the $^{15}\text{N}(i)$ /NH(i) chemical shifts of residue i . Finally, the 3D HCCH-COSY and HCCH-TOCSY experiments^{28,38} can be used to confirm and obtain complete ^1H and ^{13}C assignments of the side chains.

The power of 4D heteronuclear NMR spectroscopy for unraveling interactions that would not have been possible in lower dimensional spectra is illustrated in Figure 5 by the $^{13}\text{C}/^{13}\text{C}$ -edited NOESY spectrum of interleukin-1 β .²⁶ Figure 5(a) shows a small portion of the aliphatic region between 1 and 2 ppm of a conventional 2D NOESY spectrum of interleukin-1 β . The overlap is so great that no single, individual cross peak can be resolved. One might therefore wonder just how many NOE interactions are actually superimposed, for example, at the ^1H chemical shift coordinates of the letter X at 1.39 (F_1) and 1.67 (F_2) ppm. A $^1\text{H}(F_2)$ – $^1\text{H}(F_4)$ plane of the 4D spectrum at $\delta^{13}\text{C}(F_1)$, $\delta^{13}\text{C}(F_3) = 44.3$ ppm, 34.6 ppm is shown in Figure 5(b) and the square box at the top right-hand side of this panel encloses the region between 1 and 2 ppm. Only two cross peaks are present in this region, and the arrow points to a single NOE between the C- γ ,H and C- β ,H protons of Lys-77 with the same ^1H chemical shift coordinates as the letter X in panel A. All the other NOE interactions at the same ^1H chemical shift coordinates can be determined by inspection of a single $^{13}\text{C}(F_1)$ – $^{13}\text{C}(F_3)$ plane taken at $\delta^1\text{H}(F_2)$, $\delta^1\text{H}(F_4)$

$= 1.39$ ppm, 1.67 ppm. This reveals a total of seven NOE interactions superimposed at the ^1H chemical shift coordinates of the letter X. Another feature of the 4D spectrum is illustrated by the two $^1\text{H}(F_2)$ – $^1\text{H}(F_4)$ planes at different F_1 and F_3 ^{13}C frequencies shown in Figure 5(c) and (b). In both cases, there are cross peaks involving protons with identical or near-identical chemical shifts, namely that between proline (Pro)-91(C- α ,H) and tyrosine (Tyr)-90(C- α ,H), diagnostic of a *cis*-Pro, in Figure 5(c), and between phenylalanine (Phe)-99(C- β b,H) and methionine (Met)-95(C- γ ,H) in Figure 5(d). These interactions could not be resolved in either a 2D spectrum or a 3D ^{13}C -edited spectrum as they would lie on the spectral diagonal (i.e. the region of the spectrum corresponding to magnetization that has not been transferred from one proton to another). In the 4D spectrum, however, they are easy to observe, provided, of course, that the ^{13}C chemical shifts of the directly bonded ^{13}C nuclei are different.

Because the number of NOE interactions present in each $^1\text{H}(F_4)$ – $^1\text{H}(F_2)$ plane of 4D $^{13}\text{C}/^{15}\text{N}$ or $^{13}\text{C}/^{13}\text{C}$ -edited NOESY spectra is so small, the inherent resolution in a 4D spectrum is extremely high, despite the low level of digitization. Indeed, spectra with equivalent resolution can be recorded at magnetic field strengths considerably lower than 600 MHz, although this would obviously lead to a reduction in sensitivity. Further, it can be calculated that 4D spectra with virtual lack of resonance overlap and good sensitivity can be obtained on proteins with as many as 400 residues. Thus, once complete ^1H , ^{15}N , and ^{13}C assignments are obtained, analysis of 4D spectra should permit the automated assignment of almost all NOE interactions.

5 CONCLUSION

In this article we have summarized the recent developments in heteronuclear 3D and 4D NMR which have been designed

Figure 6 Summary of Correlations Observed in the 3D Double and Triple Resonance Experiments used for Sequential and Side-Chain Assignments

Experiment	Correlation	<i>J</i> coupling
¹⁵ N-edited HOHAHA	C- α ,H(<i>i</i>)- ¹⁵ N(<i>i</i>)-NH(<i>i</i>)	³ <i>J</i> (H,N- α) ($\approx$ 3–11 Hz)

to extend the NMR methodology to medium-sized proteins in the 15–30 kDa range.⁸ The underlying principle of this approach consists of extending the dimensionality of the spectra to obtain dramatic improvements in spectral resolution while simultaneously exploiting large heteronuclear couplings to circumvent problems associated with larger linewidths. A key feature of all these experiments is that they do not result in any increase in the number of observed cross peaks relative to their 2D counterparts. Hence, the improvement in resolution is achieved without raising the spectral complexity, rendering data interpretation straightforward. Thus, for example, in 4D heteronuclear-edited NOESY spectra, the NOE interactions between proton pairs are labeled not only by the ¹H chemical shifts but also by the corresponding chemical shifts of their directly bonded heteronuclei in four orthogonal axes of the spectrum. Also important in terms of practical applications is the high sensitivity of these experiments, which makes it feasible to obtain high-quality spectra in a relatively short time frame on 1–2 mM protein samples uniformly labeled with ¹⁵N and/or ¹³C.

Just as 2D NMR opened the application of NMR to the structure determination of small proteins of less than about 100 residues, 3D and 4D heteronuclear NMR provide the means of extending the methodology to medium-sized proteins in the 150–300 residue range. Indeed, the determination in 1991 of the first high-resolution structure of a protein in the 15–20 kDa range, namely the cytokine interleukin-1 β (153 residues and 18 kDa), using 3D and 4D heteronuclear NMR³⁹ demonstrated beyond doubt that the technology is now available for obtaining the structures of such medium-sized proteins at a level of accuracy and precision that is comparable to the best results attainable for small proteins. Subsequently, a number of other medium-sized protein structures have been determined using these methods, including interleukin-4,^{40–42} glucose permease IIA,⁴³ a complex of calmodulin with a target peptide,⁴⁴ a complex of cyclophilin and cyclosporin A,⁴⁵ and specific complexes of the transcription factor GATA-1⁴⁶ and the Antennapedia homeodomain⁴⁷ with their DNA target sites.

1 INTRODUCTION

The widespread application of NMR in the study of macromolecular structure is to a large extent the result of the ^1H - ^1H nuclear Overhauser effect (NOE), whereby it is possible to obtain distance information relating spatially proximate protons (see *Nuclear Overhauser Effect*). For reasonably small molecules (for example, proteins consisting of ~ 100 or fewer residues) this information is readily available from two dimensional (2D) homonuclear NOESY spectra which consist of cross peaks, with intensities related to the distance between the participating spins¹ (see also *NOESY* and *Biological Macromolecules: Structure Determination in Solution*). Because NOE peaks between a particular proton and all other protons within a radius of approximately 0.5 nm can, in principle be observed, the number of potential NOE cross peaks increases rapidly with molecular weight. This gives rise to considerable overlap in 2D NOE spectra of large molecules (>10 kDa), making it difficult to assign cross peaks and to obtain accurate distance information. An elegant approach to removing cross-peak overlap in 2D NOE spectra is to resolve the 2D spectrum along a third frequency dimension, the ^{15}N or ^{13}C chemical shift of the heteronucleus directly attached to one of the protons participating in the NOE transfer^{2,3} (see also *Three- and Four-Dimensional Heteronuclear Magnetic Resonance*). Such three-dimensional heteronuclear chemical shift correlated-NOESY spectra contain the same numbers of cross peaks as in a regular 2D NOESY spectrum, but the information content of these spectra (i.e., the cross peaks) is dispersed over the chemical shift range of the heteronucleus. Because of the low natural abundance of ^{15}N and ^{13}C , isotopic enrichment is necessary in order to obtain spectra with high sensitivity.^{2,4}

Figure 1 illustrates the resolving power of ^{15}N -edited 3D heteronuclear NOE spectroscopy. In (a), a region from the regular 2D NOESY spectrum of the protein staphylococcal

Figure 1 Comparison of NH, C_αH cross peak regions from 2D NOESY and 3D NOESY-HMQC experiments recorded at 500 MHz on a 1.5 mM sample of ^{15}N -labeled staphylococcal nuclease in 90% H_2O using a 125 ms NOE mixing time. (a) Regular 2D NOESY spectrum; (b) Corresponding region in a slice from the 3D NMR spectrum, where (^1H ,NH) cross peaks are separated according to the ^{15}N chemical shift of the amide nitrogen one-bond-coupled to the NH proton. The section displays NH, C_αH correlations only for those amides that have an ^{15}N chemical shift of 122.3 ± 0.3 ppm. The 3D data set was collected as a $128 \times 32 \times 256$ complex matrix (t_1, t_2, t_3). Sixteen transients were accumulated for each FID, and the total experimental time was about 64 h. Data were zero filled prior to Fourier transformation to yield a $256 \times 64 \times 512$ data matrix (F_1, F_2, F_3) for the absorptive part of the spectrum. (Source: A. Bax, *Annu. Rev. Biochem.*, 1989, **58**, 223)

nuclease (18 kDa) is illustrated. In (b), the corresponding region is shown illustrating NOEs to NH protons attached to ^{15}N nuclei resonating at 122.3 ppm. The simplification is clearly evident.

The simplification of a crowded NOESY spectrum as a result of the resolving power of the heteronuclear chemical shift enables the unambiguous assignment of many of the cross peaks, facilitates the use of automated peak picking and assignment methods, and significantly increases the effective molecular weight limitations of NMR. The method has been used for the structure elucidation of proteins having molecular weights as large as ~ 25 kDa,^{5,6} RNA,⁷ and oligosaccharides.⁸ In the following sections, descriptions of many of the pulse sequences currently in use are given, with emphasis on the 3D NOESY-HMQC sequence and improved versions of NOESY-HSQC with pulsed field gradients. In addition, protein applications of these experiments are highlighted.

2 HMQC(HSQC)-NOESY AND NOESY-HMQC (HSQC) EXPERIMENTS

The heteronuclear correlated 3D NOESY experiment consists of elements of (i) the regular 2D ^1H - ^1H NOESY

experiment and (ii) the proton-detected heteronuclear chemical shift correlation experiment. The latter element can be of the HMQC (heteronuclear multiple quantum correlation)⁹ or HSQC (heteronuclear single quantum correlation)¹⁰ variety, giving rise to 3D NOESY—HMQC, 3D HMQC—NOESY or 3D NOESY—HSQC, 3D HSQC—NOESY experiments, respectively. In these heteronuclear three-dimensional experiments, the flow of magnetization is controlled by the editing effect of the heteronucleus. In what follows, a brief discussion of the HMQC—NOESY¹¹ experiment will be provided, followed by a more detailed examination of the NOESY—HMQC¹² scheme. In subsequent sections, some HSQC versions of the experiments will be described.

2.1 3D HMQC—NOESY

Figure 2(a) illustrates one version of the HMQC—NOESY pulse scheme.¹¹ In order to ensure maximum sensitivity, magnetization originates on the sensitive proton spin, and proton magnetization is also detected during acquisition (t_3). Proton magnetization is recorded during t_1 , with the effects of the large one-bond ^1H – X scalar coupling refocused through the action of the 180° X pulse applied in the middle of the t_1 evolution period. Subsequently, antiphase magnetization is generated during the τ ($\leq [2J_{\text{HX}}]^{-1}$) delay and converted into ^1H –X double and zero quantum coherence by the application of the first 90° X pulse. The chemical shift of the heteronucleus is recorded during the t_2 delay. The ^1H 180° pulse applied in the center of the t_2 evolution delay interconverts zero and double quantum coherences, so that effectively only X chemical shift is allowed to evolve during this period. Subsequently, antiphase proton magnetization is regenerated with the application of the second 90° X pulse, and refocusing due to the ^1H –X scalar coupling is allowed to occur during the second τ delay. Because of the phase cycle on the first 90° X pulse, only magnetization originating from proton spins directly coupled to X spins is retained. During the mixing time, magnetization on X-nucleus attached proton spins is transferred to all protons in close proximity. Therefore, during the acquisition time t_3 , protons that resonate in the entire proton chemical shift range may be detected. Thus, for an ^{15}N -labeled protein ($\text{X} = ^{15}\text{N}$) dissolved in H_2O , the acquisition dimension is similar to the acquisition dimension of a regular 2D NOESY experiment. The final 3D spectrum consists of a set of 2D ^1H – ^1H (F_1/F_3) NOESY maps separated according to the amide ^{15}N chemical shift along the third frequency dimension (F_2). In contrast to the indirectly detected dimension of a regular 2D NOESY map, the F_1 dimension of each F_1/F_3 plane consists of signals originating only from protons attached to ^{15}N , owing to the editing effect of the HMQC part of the sequence. Despite the spectral simplification attainable with ^{15}N chemical shift separation in the third dimension, protein NH, C_αH cross peaks can be obscured if the C_αH resonates close to the water resonance. Therefore, applications of this experiment have primarily been for samples dissolved in D_2O with $\text{X} = ^{13}\text{C}$, and the reverse version, the NOESY—HMQC experiment, where the crucial NH, C_αH cross peaks are easily observed, has been the preferred choice for ^{15}N -labeled protein samples dissolved in H_2O .

Figure 2 Pulse sequences for (a) 3D HMQC—NOESY, and (b), (c) 3D NOESY—HMQC experiments. Narrow (wide) pulses are applied with a flip angle of 90° (180°). Unless otherwise indicated all pulses are applied along the x axis. All ^1H and ^{13}C pulses are applied at the highest field possible (about 20 kHz), while typical ^{15}N pulses are applied with a field of about 5–6 kHz. The delay τ is set to slightly less than $[2J(\text{X}, \text{H})]^{-1}$ to minimize relaxation losses. Quadrature in t_1 and t_2 is achieved via States–TPPI¹³ of ϕ_1 and ϕ_2 , respectively [sequences (a) and (b)], and ϕ_1 and ϕ_4 , respectively [sequence (c)]. In (b), $\tau = 4.5$ ms, and ^{15}N decoupling is achieved with a 1 kHz WALTZ-16¹⁴ decoupling field. In (c), $\tau = 3.3$ ms. During t_3 , ^{13}C decoupling is achieved with a GARP¹⁵ sequence using a 3.5–4.0 kHz field, and ^{13}CO decoupling during t_2 is achieved with a SEDUCE-1¹⁶ field (about 1.5 kHz at peak height) centered at 175 ppm. The ^{13}C 180° pulse in the center of t_1 is of the composite variety. The phase cycling employed in (a) is $\phi_1 = 2(x), 2(-x)$; $\phi_2 = x, -x$; Rec. = $x, 2(-x), x$; the phase of the last ^1H pulse is incremented by 90° with the receiver phase after every four transients. That in (b) is $\phi_1 = x, -x$; $\phi_2 = 2(x), 2(-x)$; Rec. = $x, 2(-x), x$. That in (c) is $\phi_1 = x, -x$; $\phi_2 = 2(x), 2(-x)$; $\phi_3 = 2(y), 2(-y)$; $\phi_4 = 8(x), 8(-x)$; $\phi_5 = 4(x), 4(-x)$; Rec. = $4(x, -x), 4(-x, x)$. [Adapted from (a) Fesik and Zuiderweg;¹¹ (b) Marion et al.,¹² and (c) Ikura et al.¹⁷]

2.2 3D ^{15}N -Edited NOESY—HMQC

Figure 2(b) illustrates the pulse scheme used to record 3D ^{15}N -edited NOESY—HMQC spectra of ^{15}N -labeled molecules.¹² The flow of magnetization during the course of the pulse sequence is conveniently described using the product operator formalism.¹⁸ A simplified description of the magnetization transfer events is presented here. Let $\hat{I}_a$ and $\hat{I}_b$ be spin operators for two protons in close proximity, with only spin b coupled to an ^{15}N spin, denoted by the operator $\hat{N}$. The effects of relaxation during all delays, with the exception of the mixing time, are neglected. At point a in the pulse scheme of Figure 2(b), the equilibrium density operator is given by

$\hat{I}_{az}$ and $\hat{I}_{bz}$ for spins a and b respectively. The behavior of magnetization from point a to the beginning of the mixing period T_m (point c) is described by

$$\begin{array}{lcl} \hat{I}_{az} \{a\} & \xrightarrow{90^\circ H} & -\hat{I}_{ay} \xrightarrow{t_1} -\hat{I}_{ay} \cos(\omega_a t_1) + \hat{I}_{ax} \sin(\omega_a t_1) \{b\} \\ \hat{I}_{bz} \{a\} & & -\hat{I}_{by} \xrightarrow{t_1} -\hat{I}_{by} \cos(\omega_b t_1) + \hat{I}_{bx} \sin(\omega_b t_1) \{b\} \\ & & \xrightarrow{90^\circ H} -\hat{I}_{az} \cos(\omega_a t_1) \{c\} \\ & & -\hat{I}_{bz} \cos(\omega_b t_1) \{c\} \end{array} \quad (1)$$

where the letters in curly brackets $\{ \}$ denote the positions in the sequence where the appropriate density operators apply and ω_i is the resonance frequency of spin i (a, b). Note that the effects of ^1H - ^{15}N scalar coupling are refocused by the end of the t_1 period due to the application of the ^{15}N 180° pulse in the center of this delay. Depending on the relative phases of the first two ^1H 90° pulses, either the cosine- or the sine-modulated component of magnetization is stored along the z axis at point c . One approach to obtaining quadrature in F_1 is to store both components in separate memory locations and subsequently combine them by the method of States et al.¹⁹ In what follows, only the first line of the phase cycle that appears in the legend to Figure 2(b) is assumed (i.e., $\phi_1 = \phi_2 = x$). In the case of macromolecular applications, the transverse components of magnetization [e.g., $\hat{I}_{ax} \sin(\omega_a t_1)$ and $\hat{I}_{bx} \sin(\omega_b t_1)$] that are present at the beginning of the mixing period decay rapidly as a result of short transverse relaxation times, and have therefore been omitted from equation (1). The use of a pulsed field gradient during this delay and/or the appropriate phase cycling can eliminate signals arising from such terms.

During the mixing period T_m , magnetization is transferred between proximate protons:

$$\begin{array}{lcl} -\hat{I}_{az} \cos(\omega_a t_1) \{c\} & \xrightarrow{T_m} & -A \hat{I}_{az} \cos(\omega_a t_1) - A' \hat{I}_{bz} \cos(\omega_a t_1) \{d\} \\ -\hat{I}_{bz} \cos(\omega_b t_1) \{c\} & & -B \hat{I}_{bz} \cos(\omega_b t_1) - B' \hat{I}_{az} \cos(\omega_b t_1) \{d\} \end{array} \quad (2)$$

where A, A', B , and B' are constants that depend on the mixing time, the inverse sixth power of the distance between spins a and b and the motional properties of the internuclear vector connecting spins a and b . The values of A, A', B , and B' are easily obtained by solving the set of coupled differential equations that describe cross relaxation between spins a and b . Details can be found in the text by Noggle and Schirmer,²⁰ and will not be repeated here. In general, $A' = B'$. Since only proton b is attached to a nitrogen spin N , the only terms of the density operator that give rise to observable magnetization after the HMQC portion of the sequence (with the appropriate phase cycling of ϕ_2) are those proportional to $\hat{I}_{bz}$. Following the conversion into transverse proton magnetization by the proton 90° pulse at point d in the sequence, these terms evolve into proton magnetization that is antiphase with respect to spin N during the first τ period:

$$\begin{array}{lcl} -A' \hat{I}_{bz} \cos(\omega_a t_1) \{d\} & \xrightarrow{90^\circ H} & A' \hat{I}_{by} \cos(\omega_a t_1) \{e\} \\ -B \hat{I}_{bz} \cos(\omega_b t_1) \{d\} & & B \hat{I}_{by} \cos(\omega_b t_1) \{e\} \\ & & \xrightarrow{\tau} -A' 2 \hat{I}_{bx} \hat{N}_z \cos(\omega_a t_1) \{f\} \\ & & -B 2 \hat{I}_{bx} \hat{N}_z \cos(\omega_b t_1) \{f\} \end{array} \quad (3)$$

In the derivation of equation (3) the delay τ has been set equal to $[2J(\text{N,H})]^{-1}$. In addition, ^1H chemical shift evolution during τ has been neglected, since the ^1H 180° pulse applied in the center of the t_2 evolution period refocuses the effect of proton chemical shifts. The 90° ^{15}N pulse at point f creates

zero and double quantum terms, which subsequently evolve in t_2 to give N -spin chemical shift labeling:

$$\begin{array}{lcl} -A' 2 \hat{I}_{bx} \hat{N}_z \cos(\omega_a t_1) \{f\} & \xrightarrow{90^\circ N} & A' 2 \hat{I}_{bx} \hat{N}_y \cos(\omega_a t_1) \{g\} \\ -B 2 \hat{I}_{bx} \hat{N}_z \cos(\omega_b t_1) \{f\} & & B 2 \hat{I}_{bx} \hat{N}_y \cos(\omega_b t_1) \{g\} \\ & & \xrightarrow{\frac{1}{2} t_2 180^\circ H \frac{1}{2} t_2} A' 2 \hat{I}_{bx} \hat{N}_y \cos(\omega_a t_1) \cos(\omega_N t_2) \{h\} \\ & & B 2 \hat{I}_{bx} \hat{N}_y \cos(\omega_b t_1) \cos(\omega_N t_2) \{h\} \end{array} \quad (4)$$

where the $\sin(\omega_N t_2)$ terms have been neglected, since for $\phi_2 = x$ these terms do not contribute to the observed signal.

After the second 90° N pulse, the double and zero quantum terms are converted into antiphase proton magnetization, which is allowed to refocus into observable proton magnetization during the second τ delay. Evolution during the acquisition time t_3 then yields

$$\begin{array}{lcl} A' \hat{I}_{by} \cos(\omega_a t_1) \cos(\omega_N t_2) \{j\} \\ B \hat{I}_{by} \cos(\omega_b t_1) \cos(\omega_N t_2) \{j\} \\ \xrightarrow{t_3} A' \hat{I}_{by} \cos(\omega_a t_1) \cos(\omega_N t_2) \cos(\omega_b t_3) (\text{cross peak}) \\ B \hat{I}_{by} \cos(\omega_b t_1) \cos(\omega_N t_2) \cos(\omega_b t_3) (\text{diagonal peak}) \end{array} \quad (5)$$

for the y component of magnetization. Similar relations hold for the x component of magnetization.

Fourier transformation of the resultant signal gives rise to cross peaks at (ω_a, ω_b) located in a slice through the 3D data set with ^{15}N frequency ω_N . In addition, a diagonal peak at (ω_b, ω_b) in the same slice is also observed. That is, a NOE cross peak at the chemical shift of the proton from which magnetization originated (F_1), the chemical shift of the destination NH proton (F_3), and the shift of the ^{15}N nucleus directly coupled to the NH spin (F_2) are obtained. Unlike 2D ^1H - ^1H NOESY maps, which are symmetrical, ^{15}N -edited maps are asymmetrical, since the ^{15}N editing that occurs during the course of the pulse scheme ensures that only the transfer of magnetization to an NH proton is observed. Note that the crucial ($C_\alpha\text{H}$, NH) NOE connectivities occur as (F_1, F_3) cross peaks, and can be detected in a straightforward manner without interference from the residual water signal, as shown in Figure 1.

2.2.1 Practical Aspects of 3D Heteronuclear-Edited NOESY Pulse Schemes

2.2.1.1 Water Suppression. Because ^{15}N -edited NOESY experiments provide crucial information linking NH protons to neighboring proton spins, these experiments must be performed on protein samples dissolved in H_2O . Water suppression schemes must therefore be employed to minimize the dynamic range problem that the use of this solvent presents. Suppression of the intense water signal is often achieved through the use of a weak coherent presaturation field (≤ 30 Hz) applied during the relaxation delay prior to the first 90° excitation pulse. In addition, saturation of the water resonance can proceed during the mixing time. In an early implementation of the experiment, Kay et al.²¹ described the use of an off-resonance DANTE²² sequence to suppress the water, with the carrier positioned in the center of the NH region. In addition, an off-resonance jump and return sequence of the type, $45^\circ_x - \tau - 45^\circ_x$, where τ is set according to the relation $\tau = (2 \times \text{offset of } \text{H}_2\text{O})^{-1}$ and where the carrier is centered in the NH region, was inserted in place of the 90° ^1H pulse applied immediately after the mixing period.

The use of presaturation has been shown significantly to decrease the intensity of cross peaks originating from labile

protons. This can lead to a significant overall decrease in the intensity of the protein envelope due to the effect of saturation transfer. We have recently shown in applications involving the cellulose binding domain of a cellulase from *Cellulomonas fimi* (CBD, a dimer of monomers of molecular weight 11 kDa) that the use of a presaturation field (30 Hz) applied for 1 s prior to the start of the experiment can decrease the protein envelope by as much as 40%.²³ Montelione and co-workers have recently compared a number of different water suppression schemes as a function of sample pH, showing that presaturation gives the largest decrease in signal.²⁴ Grzesiek and Bax have also emphasized the importance of not saturating the water resonance,²⁵ and have suggested a strategy involving the use of pulsed field gradients and selective pulses on the water to ensure the placement of water magnetization on the +z axis prior to the start of the detection period in each transient. Pulse schemes incorporating field gradients are discussed in Section 3.

2.2.1.2 Phasing in the Indirectly Detected Dimensions (F_1 , F_2). After Fourier transformation, the indirectly detected dimensions can be phased using calculated phase parameters. The approach of choice is to set the initial values of t_1 and t_2 [$t_1(0)$, $t_2(0)$] prior to running the experiment in order to obtain spectra having first-order phase corrections of either 0° or 180°. This ensures that flat baselines are obtained.²⁶ It is straightforward to calculate the appropriate values for $t_1(0)$ and $t_2(0)$ for a given pulse sequence, and in what follows we consider the ¹⁵N NOESY—HMQC sequence of Figure 2(b). Noting that, to a good first approximation, a 90° pulse can be replaced by a delta function pulse followed by a delay of $(2/\pi)\tau_{90}$, where τ_{90} is the 90° pulse width,²⁷ the sampling delay in the t_1 dimension (NOESY portion of the sequence) is given by

$$sd(t_1) = \frac{4}{\pi} \tau_{90}(\text{H}) + \tau_{180}(\text{N}) + t_1(0) \quad (6)$$

where $\tau_{90}(\text{H})$ is the ¹H 90° pulse width and $\tau_{180}(\text{N})$ is the ¹⁵N 180° pulse width. The sampling delay in the t_2 dimension (the HMQC portion of the sequence) is given by

$$sd(t_2) = \frac{4}{\pi} \tau_{90}(\text{N}) + \tau_{180}(\text{H}) + t_2(0) \quad (7)$$

where $\tau_{180}(\text{H})$ is the duration of the ¹H 180° pulse in the middle of t_2 .²¹

If the data are acquired in the States format, the linear phase correction that must be applied in F_i ($i = 1, 2$) is given by $sd(t_i) \times 360/\Delta t_i$, where Δt_i is the dwell time in the t_i th dimension.²⁶ In order to ensure that no net phase correction is applied in the center of the spectrum, a zeroth-order phase correction of $-0.5sd(t_i) \times 360/\Delta t_i$ must be applied as well. It should be clear that if the sampling is delayed by exactly $\frac{1}{2} \Delta t_i$, a linear phase correction of 180° is required across the spectrum. In this case, aliased peaks will be of opposite sign relative to peaks that are not aliased.

2.3 Application to Uniformly ¹³C-Enriched Molecules

The ¹³C NOESY—HMQC and HMQC—NOESY experiments provide valuable distance information linking two carbon-bound protons. For reasons of sensitivity, these experiments, like the ¹⁵N versions discussed previously, are performed on highly enriched, uniformly labeled samples. The

use of highly enriched ¹³C molecules results in a significant increase in the linewidths of the attached proton(s). The heteronuclear dipolar coupling between a directly coupled ¹³C—¹H pair is approximately a factor of two larger than the coupling from an ¹⁵N—¹H spin pair. A second complication associated with the use of uniform labeling is the introduction of homonuclear carbon—carbon scalar couplings, varying from approximately 60 Hz for ¹³C_α—¹³CO couplings to approximately 35 Hz for aliphatic carbons. These couplings can significantly degrade the resolution available in spectra. Fortunately, the large chemical shift difference between carbonyl spins and the aliphatic spins allows for the efficient decoupling of the ¹³C_α—¹³CO scalar interaction using selective shaped decoupling schemes such as SEDUCE-1.¹⁶ In order to minimize the effects of the aliphatic couplings, maximum acquisition times $t_{\text{max}} \approx 10$ ms are chosen in the carbon dimension, where $t_{\text{max}} < [2J(\text{C,C})]^{-1}$ and $J(\text{C,C})$ is the aliphatic scalar coupling constant. While this does limit resolution in the carbon dimension, it must be kept in mind that in many protein applications, the ¹³C T_2 values are on the order of only 10–20 ms.

Figure 2(c) illustrates a pulse scheme for the ¹³C NOESY—HMQC sequence.¹⁷ The flow of magnetization is essentially identical to that discussed in connection with the ¹⁵N-edited version of the experiment, and will therefore only be summarized as follows:

$$^1\text{H}_i(t_1) \xrightarrow{\text{NOE}} ^1\text{H}_j \xrightarrow{J(\text{C,H})} ^{13}\text{C}_j(t_2) \xrightarrow{J(\text{C,H})} ^1\text{H}_j(t_3) \quad (8)$$

with chemical shift evolution recorded during t_1 , t_2 , and t_3 . Note that the reverse pathway, where magnetization originates on spin j and is transferred via the NOE to spin i , is also possible (providing that both proton spins i and j are bound to ¹³C nuclei), so that symmetry related cross peaks are observed at (H_i , C_j , H_j) and (H_j , C_i , H_i). For the case of distinct carbons C_i and C_j , the symmetry related cross peaks will appear on different slices in the 3D data set. These symmetry related pairs are extremely helpful in the unambiguous assignment of NOE cross peaks.

Because of the large carbon chemical shift range, extending from approximately 10 ppm for methyl carbons to 140 ppm for aromatic carbons, many of the cross peaks in the 3D ¹³C-edited NOESY spectra are aliased in the carbon dimension. Typically, a carbon spectral width of 3–4 kHz is employed with the carbon carrier positioned at about 65 ppm. The sampling delay in the carbon dimension is adjusted so that a 180° first-order phase correction is required. In this way, cross peaks that have been aliased an odd number of times are 180° out of phase relative to peaks that are not aliased or have been aliased an even number of times.

Figure 3 illustrates the power of the 3D ¹³C NOESY—HMQC experiment in removing the overlap in the crowded aliphatic region of the regular NOESY spectrum. A comparison of a slice from the 3D data set recorded on the protein calmodulin (MW = 16.7 kDa) with the same region of a 2D spectrum clearly shows the resolving power in increasing the dimensionality from two to three.¹⁷

Up to this point in our discussion, we have focused on a number of the basic NOESY—HMQC and HMQC—NOESY pulse sequences, as they appeared in the literature, prior to the development of pulsed field gradient methods. It is generally the case that these experiments can be significantly improved

Figure 3 Comparison of (a) a section of an (F_1 , F_3) slice taken at $F_2 = 17.8$ ppm from the 500 MHz 3D ^{13}C NOESY-HMQC spectrum of a 1.5 mM 95% ^{13}C -labeled sample of calmodulin, 6.2 mM Ca^{2+} and (b) the same region of the 600 MHz regular 2D NOESY spectrum of a 1.5 mM unlabeled calmodulin sample, 6.2 mM Ca^{2+} , using mixing times of 120 ms. The 3D data set was collected as a matrix of $128^* \times 64^* \times 512$ points (t_1 , t_2 , t_3) in about 60 h (* denotes complex points). (Reproduced by permission of Academic Press from M. Ikura, L. E. Kay, R. Tschudin, and A. Bax, *J. Magn. Reson.*, 1990, **86**, 204)

with the incorporation of field gradients, and the use of this novel technology in such applications is discussed in the next section.

3 PULSED FIELD GRADIENT METHODS

Recent developments in pulsed field gradient technology have led to many useful applications in high-resolution NMR spectroscopy (see *Field Gradients and Their Application*). The use of gradients allows for the efficient removal of the intense water signal in the case of samples dissolved in H_2O ,²⁸ the elimination of undesired coherences that produce artifacts,²⁹ a decrease in the number of phase cycling steps, thereby reducing the overall data collection time for sufficiently concentrated samples,³⁰ and the selection of

particular coherence transfer pathways.³¹ By incorporating field gradient pulses into many of the experiments discussed earlier, data sets with improved suppression of solvent and artifacts can be obtained. A brief discussion of two heteronuclear-edited gradient NOESY experiments is presented; an ^{15}N -edited NOESY-HMQC experiment developed by Vuister et al.³⁰ that can be recorded using only a single transient for each ^{15}N data point, and a simultaneous ^{15}N -, ^{13}C -edited NOESY-HSQC experiment.³²

3.1 Gradient 3D NOESY-HMQC

A pulse scheme for the gradient-enhanced 3D NOESY-HMQC experiment developed by Vuister and co-workers is shown in Figure 4(a).³⁰ In this experiment, the coherence

Figure 4

Figure 4 Pulse sequences for (a) the gradient NOESY–HMQC and (b) the gradient CN NOESY–HSQC experiments. Narrow (wide) pulses are applied with a flip angle of 90° (180°). Unless otherwise indicated, all pulses are applied along the x axis. All ^1H and ^{13}C pulses are applied at the highest field possible (about 20 kHz), while typical ^{15}N pulses are applied with a field of about 5–6 kHz. In (a), quadrature in t_1 is achieved via States–TPPI¹³ of ϕ_1 ; $\tau = 4.5$ ms. Gradients are of 0.8 ms in duration and are sine-bell in shape. Gradient strengths are $g_{1x} = g_{2x} = 63.7 \text{ mT m}^{-1}$, $g_{3x} = -12.9 \text{ mT m}^{-1}$, $g_{1z} = g_{2z} = 20.5 \text{ mT m}^{-1}$, $g_{3z} = -4.2 \text{ mT m}^{-1}$, and $G_y = 19.7 \text{ mT m}^{-1}$. The G_z gradient in T_m is applied for 0.4 ms and cycled through 7, 21, 35, and 49 mT m^{-1} in successive transients. In (b), the x , y ^1H purge pulses immediately after the acquisition are applied for 8 and 5 ms respectively, with a 10 kHz field. The ^{13}C pulses are centered at 67 ppm. The first 180° ^{13}C pulse is a composite $90^\circ_x 180^\circ_y 90^\circ_x$ pulse. The GARP decoupling is preceded by high-power ^{15}N and ^{13}C pulse pairs as described by Bax et al.³³ The delays τ_a and τ_b were both set to 1.7 ms. Quadrature in t_1 and t_2 is achieved via States–TPPI¹³ of ϕ_1 and ϕ_2 , respectively. The diagram at the bottom of the figure illustrates the adjustment of timing delays in order to obtain a 180° first-order phase correction in F_2 for both ^{15}N - and ^{13}C -modulated data. The first ^{13}C pulse, of duration pwc, commences at $\delta_1 = [(\pi - 2)/\pi](\text{pwn} - \text{pwc})$ after the start of the ^{15}N ϕ_2 pulse of duration pwn, while the ^{13}C pulse immediately after the t_2 evolution period begins $\delta_2 = (2/\pi)(\text{pwn} - \text{pwc})$ after the start of the corresponding ^{15}N pulse ($\text{pwc} < \text{pwn}$). By setting the initial t_2 value, $t_2(0) = (2\text{SW}_2)^{-1} - [(4/\pi)\text{pwn} + 2\text{pw}]$, where SW_2 is the spectral width in the ^{13}C and ^{15}N dimensions and pw is the ^1H 90° pulse width, a 180° first-order phase correction in F_2 is obtained. The following phase cycle is employed: $\phi_1 = 4(x), 4(-x)$; $\phi_2 = 8(x), 8(-x)$; $\phi_3 = (x, y, -x, -y)$; $\phi_4 = 4(x), 4(-x)$; rec. = $(x, -y, -x, y, -x, y, x, -y, -x, y, x, -y, x, -y, -x, y)$. The durations and strengths of the gradients are $g_1 = (3 \text{ ms}, 150 \text{ mT m}^{-1})$, $g_2 = (1 \text{ ms}, 200 \text{ mT m}^{-1})$, $g_3 = g_4 = (1 \text{ ms}, 80 \text{ mT m}^{-1})$, $g_5 = (4 \text{ ms}, 300 \text{ mT m}^{-1})$, $g_6 = (3 \text{ ms}, -180 \text{ mT m}^{-1})$, and $g_7 = g_8 = (1 \text{ ms}, 80 \text{ mT m}^{-1})$. A delay of at least $50 \mu\text{s}$ between the application of a gradient pulse and the subsequent application of an rf pulse is employed. All gradient pulses are rectangular in shape. (Adapted from (a) Vuister et al.³⁰ and (b) Pascal et al.³²)

transfer pathway whereby magnetization passes through nitrogen is selected with the use of the appropriate pulsed field gradients. Because it is not possible for water magnetization to traverse this pathway, excellent levels of water suppression can be achieved. The gradients g_1 – g_3 are employed for coherence transfer selection by adjusting their strengths according to the ratio $g_1:g_2:g_3 = 4.94:4.94:1.0$ ($\gamma_{\text{H}}/\gamma_{\text{N}} = -9.88$), while the gradient pair (G_y) applied on opposite sides of the ^1H 180° pulse in the middle of the t_2 period ensures that any artifacts that could be created owing to imperfections in this pulse are eliminated.²⁹ In this experiment, pure amplitude-modulated data are recorded in the t_1 dimension in the normal fashion. However, the use of gradients g_1 – g_3 results in the generation of phase-modulated data in the t_2 dimension, and therefore spectra must be presented in the absolute value mode after processing. Note that phase cycling is not necessary in the present application. Thus, it is possible to obtain spectra in short periods of measuring time, assuming that the sample is sufficiently concentrated so that the signal-to-noise ratio is not limiting. For this reason, this experiment is useful for kinetic studies and for studies of molecules that are stable for only short periods of time. The requisite absolute value representation of the data, however, does result in a considerable loss in resolution, which is especially critical in macromolecular applications.

3.2 Simultaneous ^{15}N -, ^{13}C -Edited NOESY

An advantage associated with the development of pulsed field gradient technology is the potential of recording all spectra necessary for a protein structure determination using only a single ^{15}N -, ^{13}C -labeled sample dissolved in H_2O . In addition to minimizing the number of samples necessary for a structure determination, the use of just a single sample also ensures that ambiguities arising from a comparison of data recorded on a number of different samples prepared with slight differences can be minimized. This is important in order to maximize the efficiency of automated or semi-automated assignment and structure determination approaches.

The CN NOESY–HSQC experiment illustrated in Figure 4(b) provides NOEs between any two proximate protons in ^{15}N -, ^{13}C -labeled proteins separated by the chemical shift of the heteroatom to which the destination proton

is attached.³² Because spectra are recorded on samples dissolved in H_2O , valuable NOEs involving NH protons are also observed.

Pulsed field gradients are used in this experiment to aid in the removal of artifacts as well as to assist in water suppression. A detailed description of the utility of each gradient is found elsewhere.³² Gradients g_5 and g_6 are particularly important for water suppression, since, during the time of their application, the magnetization of interest is of the form $\hat{I}_z \hat{X}_z$, where $\hat{I}_z$ and $\hat{X}_z$ are the z components of ^1H and ^{15}N or ^{13}C magnetizations, respectively, while water magnetization is present in the transverse plane and hence is dephased by the combined action of the gradient pair (g_5, g_6). For this reason, an HSQC-type transfer of magnetization from ^1H to X must be employed rather than an HMQC transfer.^{34,35} Figure 5 illustrates the quality of water suppression obtained with the present sequence with the ^{15}N pulses set to zero (i.e., ^{13}C NOESY–HSQC) for a 1.5 mM sample of the cellulose binding domain CBD. The noise from the residual water obscures a region of approximately ± 0.2 ppm around the water line (4.8 ppm) in F_3 .

The basic flow of magnetization transfer in this experiment can be described by the following two independent pathways:

with chemical shifts recorded during t_1 , t_2 , and t_3 . Note that each (F_1, F_3) slice of the data set is labeled with either the ^{15}N or ^{13}C chemical shift of the heteroatom to which the destination proton is attached. For proteins, ^{13}C - and ^{15}N -bound protons generally have quite distinct chemical shifts, and therefore, with the possible exception of a few backbone or side-chain amide and aromatic protons, the extra information in these spectra relative to single ^{15}N - or ^{13}C -edited data sets does not create ambiguities in interpretation.

A particularly important feature of the CN NOESY–HSQC data set is that, for each NOE cross peak between a carbon-bound proton and a nitrogen-bound proton at position (CH,N,NH), it is possible to find a symmetry-related cross peak at (NH,C,CH). The experiment also provides NOEs

between exclusively carbon-bound or nitrogen-bound protons. Figure 6 shows a number of slices from a 150 ms CN NOESY–HSQC data set obtained on a 1.5 mM sample of the C-terminal SH2 domain from phospholipase-C γ 1 complexed with a 12-residue phosphotyrosine-containing peptide.

4 SENSITIVITY-ENHANCED VERSIONS OF 3D HETERONUCLEAR-EDITED NOESY EXPERIMENTS

In the past several years, a family of elegant pulse schemes has been developed by Cavanagh, Palmer, and Rance that offers significant improvements in sensitivity for certain classes of experiments.^{36,37} In the case of a two-dimensional experiment, for example, sensitivity gains are recognized because both the cosine- and the sine-modulated t_1 components are refocused into observable magnetization prior to detection. In this section, a description of a nongradient, sensitivity-enhanced ^{15}N -edited NOESY–HMQC experiment³⁷ is presented, followed by a discussion of a sensitivity-enhanced ^{15}N -edited NOESY–HSQC gradient experiment.³⁸ In the latter experiment, saturation of water is minimized as well by employing selective pulses on water to restore magnetization to the $+z$ axis prior to detection.

4.1 Sensitivity-Enhanced 3D ^{15}N -Edited NOESY–HMQC

Figure 7(a) illustrates the pulse scheme used to record ^{15}N -edited NOESY–HMQC spectra with increased sensitivity.³⁷ Although the sequence is slightly more complicated than the unenhanced version illustrated in Figure 2(b), the flow of magnetization throughout the experiment is easily understood with the use of the product operator formalism.¹⁸ Immediately prior to detection, the magnetization that originates on spin a and is transferred to spin b is described by

$$\hat{\rho}(\phi_2 = x) = A[-\hat{I}_{bx} \cos(\omega_N t_2) - \delta_{1,M} \hat{I}_{by} \sin(\omega_N t_2)] \cos(\omega_a t_1) \quad (11)$$

$$\hat{\rho}(\phi_2 = -x) = A[\hat{I}_{bx} \cos(\omega_N t_2) - \delta_{1,M} \hat{I}_{by} \sin(\omega_N t_2)] \cos(\omega_a t_1) \quad (12)$$

where $\hat{\rho}$ is the density operator, M is the number of protons (spins I) attached to the heterospin (spin N), A is a factor that depends, among other things, on the efficiency of transfer of I -spin magnetization from spin a to spin b , and $\delta_{1,M} = 1$ if $M = 1$ and zero otherwise. Note that separate data sets are recorded for $\phi_2 = x$ and $\phi_2 = -x$. Using the present approach, phase-modulated data are generated in the t_2 dimension, as equations (11) and (12) suggest.

In order to generate pure absorptive lineshapes, the data can be recombined by taking the sum and the difference of the data sets obtained for $\phi_2 = \pm x$ for a given value of t_2 to generate a new data set of the form

$$(11) + (12) \hat{\rho} = -\delta_{1,M} 2A \hat{I}_{by} \cos(\omega_a t_1) \sin(\omega_N t_2) (\text{SUM}) \quad (13)$$

$$(11) - (12) \hat{\rho} = -2A \hat{I}_{bx} \cos(\omega_a t_1) \cos(\omega_N t_2) (\text{DIFFERENCE}) \quad (14)$$

Note that the SUM signal is proportional to $\hat{I}_y$, while the DIFFERENCE signal is proportional to $\hat{I}_x$. For this reason, a

Figure 5 Section of an (F_1 , F_3) slice from the 3D gradient ^{13}C NOESY–HSQC spectrum recorded at 500 MHz on a 1.5 mM sample of ^{15}N -, ^{13}C -labeled CBD, pH 7.0, 90% H_2O /10% D_2O at 30 °C, displaying a region close to the water resonance. The mixing time was 150 ms and the data set was acquired as a $128 \times 32 \times 416$ complex matrix (t_1 , t_2 , t_3), in about 90 h. The data were processed to give absorptive spectra consisting of $256 \times 64 \times 1024$ points in each of (F_1 , F_2 , F_3). Residual water not eliminated by the gradients was removed using a postacquisition time domain deconvolution procedure.³⁵ Cross peaks due to either NOEs to water or exchange with labile groups are indicated with asterisks. Interresidue NOEs are labeled with the residue name. (Adapted from Muhandiram et al.³⁵)

Figure 6 Slices from a CN NOESY-HSQC data set recorded at 500 MHz on a 1.5 mM sample of the protein–peptide complex PLC γ 1 SH2-pY1021, showing pairs of ‘symmetry-related’ cross peaks for NOEs between L80NH and L77C α H (a, b) and M26NH and I55C δ H (c, d). The cross peaks are observed on planes with the appropriate F_2 chemical shift being either that of ^{15}N or ^{13}C , depending on whether the destination proton is an amide or aliphatic proton. The cross peak of interest from each slice is connected to the diagonal on the corresponding slice by a vertical line. Peaks are labeled with the atom name, and interresidue NOEs are additionally labeled with the residue name. The NOE mixing time was 150 ms, and the data set was acquired as a $128 \times 32 \times 416$ complex matrix (t_1, t_2, t_3), in about 90 h. The data set was processed to give absorptive spectra consisting of $256 \times 128 \times 1024$ points in each of (F_1, F_2, F_3). In order to optimize the resolution of the ^{15}N lines, linear prediction was employed in t_2 . The intensity of the residual water signal was minimized through the time domain deconvolution procedure discussed by Muhandiram et al.³⁵ (Reproduced by permission of Academic Press from S. M. Pascal, D. R. Muhandiram, T. Yamazaki, J. D. Forman-Kay, and L. E. Kay, *J. Magn. Reson., Ser B*, 1994, **103**, 197)

90° zeroth-order phase correction is applied to either the SUM or the DIFFERENCE data (not both) in the time domain. After these simple time-domain manipulations have been performed, a data set is obtained that contains peaks that are purely absorptive after processing using the States recipe.¹⁹ For the case where $M = 1$ (i.e., an AX ^{15}N ,NH heteronuclear spin system) the process of taking the sum and the difference of the signals described by equations (11) and (12) increases the signal intensity by a factor of two relative to signals in spectra recorded using an unenhanced sequence. The noise floor increases by a factor of $\sqrt{2}$ during this process, so that the net increase in signal-to-noise ratio is a factor of $\sqrt{2}$. Of course, this theoretical sensitivity gain does not include potential losses that can occur owing to the increased number of pulses and delays in the sequence relative to the unenhanced version. For protein applications considered to date, appreciable increases in sensitivity have been obtained. Figure 8 compares the F_1 traces from regular and sensitivity-enhanced NOESY–HMQC spectra of ^{15}N -labeled calbindin D9k (75 amino acids) in 90% $\text{H}_2\text{O}/10\%$ D_2O , with sensitivity enhancements close to the theoretical maximum of $\sqrt{2}$ realized.

4.2 Sensitivity-Enhanced Gradient 3D NOESY–HSQC

Figure 7(b) illustrates the sensitivity-enhanced 3D ^{15}N -edited NOESY–HSQC sequence with gradients used to suppress artifacts, to aid in the suppression of the intense solvent signal and to select for ^{15}N magnetization during the

nitrogen evolution time t_2 . In the selection of ^{15}N magnetization using gradients, a sensitivity enhancement approach is taken based on the nongradient sensitivity-enhanced method discussed above.²³ Sensitivity in the experiment is increased further by restoring the water signal to the $+z$ axis prior to detection²⁵ in order to minimize the saturation of water during the course of the experiment. The detailed mechanism of the experiment is reported elsewhere.³⁸ It can easily be understood how the water is stored along the $+z$ axis after each transient by noting that for mixing times T_m in excess of about 50 ms, the effect of radiation damping is such that water magnetization is restored to the $+z$ axis at point *a* in the pulse scheme in a manner independent of the phase ϕ_1 of the first ^1H 90° pulse. In order to facilitate radiation damping, ϕ_1 is phase-cycled 45°, 225° as opposed to 0°, 180° ($x, -x$). Immediately after the first ^1H 90°_y pulse (point *b* in the sequence), the water magnetization is along the *y* axis, while the signal of interest is of the form $\hat{I}_z\hat{N}_z$, where $\hat{I}_z$ and $\hat{N}_z$ are the *z* components of the NH and ^{15}N magnetizations, respectively. The water-selective pulse applied at this point rotates the (on-resonance) water magnetization to the $-z$ axis without perturbing the signal of interest. Application of the gradient g_5 immediately after the selective pulse ensures that any residual water magnetization in the transverse plane is completely dephased, thereby eliminating radiation damping at this point. It is straightforward to show that the effect of the remaining proton pulses on the water is such that water magnetization resides along the $+z$ axis at the start of the acquisition period t_3 .

Figure 7 Pulse sequences for (a) sensitivity-enhanced 3D NOESY-HMQC and (b) sensitivity-enhanced gradient 3D NOESY-HSQC experiments. Unless otherwise stated, all parameters are as in Figure 2. In both experiments, quadrature in t_1 is achieved by States-TPPI of ϕ_1 . (a) The phase cycle is $\phi_1 = x, -x$; $\phi_2 = 2(x), 2(-x)$; $\phi_3 = 2(y), 2(-y)$; Rec. = $x, 2(-x), x$. The phase of ϕ_2 is inverted after four transients, and the data are stored separately. Quadrature in t_2 is achieved using the method of States.¹⁹ (b) The shaped pulse on ^1H is a 'water'-selective 90° pulse. This pulse is either a 2 ms rectangular pulse (125 Hz field) or a 2 ms shaped pulse (270 Hz field at peak height) having the profile of a 90° SEDUCE-1 element.¹⁶ The phase cycle is $\phi_1 = x, -x$; $\phi_2 = 4(x), 4(-x)$; $\phi_3 = 2(x), 2(-x)$; $\phi_4 = x$; Rec. = $2(x, -x), 2(-x, x)$. For each t_2 increment, the phase ϕ_2 and the receiver phase are inverted. For each t_2 value, two FIDs are recorded and stored separately, with the phase ϕ_4 and the amplitude of the gradient pulse g_{11} inverted for the second FID. The delays τ , τ_a and τ_b are set to 2.4 ms ($<[4J(\text{N,H})]^{-1}$), 1.5 ms and 0.5 ms respectively. The durations and strengths of the gradients are $g_1 = (2 \text{ ms}, 100 \text{ mT m}^{-1})$, $g_2 = (0.5 \text{ ms}, 80 \text{ mT m}^{-1})$, $g_3 = g_4 = (0.75 \text{ ms}, 50 \text{ mT m}^{-1})$, $g_5 = (2 \text{ ms}, -150 \text{ mT m}^{-1})$, $g_6 = (1.25 \text{ ms}, 300 \text{ mT m}^{-1})$, $g_7 = g_8 = (0.5 \text{ ms}, 80 \text{ mT m}^{-1})$, $g_9 = g_{10} = (0.5 \text{ ms}, 50 \text{ mT m}^{-1})$, and $g_{11} = (0.125 \text{ ms}, 278 \text{ mT m}^{-1})$. The strength of g_{11} is optimized by maximizing the signal. (Adapted from (a) Palmer et al.³⁷ and (b) Zhang et al.³⁸)

A product operator description similar to that given above shows that, immediately prior to acquisition, the magnetization associated with an NH proton is given by

$$\hat{\rho}(\phi_4 = \pm x) = A \cos(\omega_a t_1) [\pm \hat{I}_{by} \cos \theta_1 + \hat{I}_{bx} \sin \theta_1] \quad (15)$$

where $\hat{I}_{bx}$ and $\hat{I}_{by}$ are the x and y components of NH magnetization, and all other symbols defined as above. The value of θ_1 is given by $\theta_1 = \omega_N t_2 + \gamma_N B_1(z) \tau_1 \pm \gamma_H B_2(z) \tau_2$ for $\phi_4 = \pm x$, where ω_N is the ^{15}N Larmor frequency, γ_i is the gyromagnetic ratio of spin i , and τ_i ($i = 1, 2$) is the duration of the z gradient pulse generating a magnetic field of magnitude B_i at position z in the sample. Assuming that

1. the gradients used to select for ^{15}N magnetization (g_6, g_{11}) are sufficiently strong that they cause complete dephasing of magnetization, and
 2. for $\phi_4 = \pm x$, the gradients are adjusted so that $\gamma_N B_1(z) \tau_1 = \mp \gamma_H B_2(z) \tau_2$,
- Equation (15) reduces to

$$\hat{\rho}(\phi_4 = \pm x) = A \cos(\omega_a t_1) [\pm \hat{I}_{by} \cos(\omega_N t_2) + \hat{I}_{bx} \sin(\omega_N t_2)] \quad (16)$$

Figure 8 Comparison of conventional (bottom trace) and sensitivity-enhanced NOESY-HMQC (top trace) spectra of the protein calbindin recorded at 500 MHz. Both experiments were acquired in the same overall time as $100 \times 32 \times 1024$ complex data sets with 16 transients per FID. The NOE mixing time was 150 ms. The figure shows F_1 cross sections for (a) Lys12 and (b) Glu35 taken at F_2, F_3 frequencies of the backbone amide ^{15}N and proton resonances, respectively. The increase in the RMS baseplane noise for the enhanced spectrum, compared with the conventional one, agrees with the theoretical value of $\sqrt{2}$. The average S/N improvements between the enhanced and conventional spectra are (a) 1.41 and (b) 1.39. (Reproduced by permission of Academic Press from A. G. Palmer, J. Cavanagh, R. A. Byrd, and M. Rance, *J. Magn. Reson.*, 1992, **96**, 416)

For each value of t_2 , data sets are recorded with $\phi_4 = x$, $\gamma_N B_1(z) \tau_1 = -\gamma_H B_2(z) \tau_2$, and $\phi_4 = -x$, $\gamma_N B_1(z) \tau_1 = \gamma_H B_2(z) \tau_2$, and stored in separate memory locations. The data are subsequently manipulated in the time domain, as described in connection with the enhanced NOESY-HMQC experiment above, to yield a purely absorptive spectrum after Fourier transformation. Enhancements in signal-to-noise ratio by a factor of as much as $\sqrt{2}$ relative to unenhanced experiments can be obtained using this approach.

5 CONCLUDING REMARKS

The development of heteronuclear, multidimensional, multi-nuclear MR spectroscopy has facilitated large numbers of structural studies of macromolecules, and has significantly increased the size of molecules that can be studied. The heteronuclear-edited NOESY experiment provides the crucial distance information necessary for these structure determinations. Presently, the interpretation of NOESY data sets is the time-consuming step in the structure determination process. Current efforts are focusing on ways of providing a more automated approach to the assignment of NOE cross peaks and the calculation of structures.

1 INTRODUCTION

Homonuclear TOCSY¹ and ROESY² experiments are essential tools for the identification of spin systems and for the measurement of internuclear distances, respectively. (ROESY has been reviewed by Bull;³ see also **ROESY** in this Encyclopedia.) TOCSY experiments rely on the transfer of polarization via J coupling, ROESY experiments rely on dipolar relaxation. Cross peaks due to slow chemical exchange are present in both experiments. The success of TOCSY and ROESY depends critically on the performance of the mixing sequence used to accomplish polarization transfer via the desired interaction. It will be shown that because of the complicated mixing sequences used, cross relaxation and J transfer cannot easily be separated. In fact, longitudinal and transverse cross relaxation and J transfer are intimately connected, and it is the aim of this article to describe handy tools to estimate the contribution of either of these interactions for a given pulse sequence. Unwanted interactions must be suppressed, since they lead to artifacts that can hamper the interpretation of the spectra. For example, transfer via J couplings alters the intensity of cross peaks in ROESY, and cross relaxation interferes with weak cross peaks in TOCSY. The offset dependence of TOCSY transfer and the offset dependence of the weight of transverse and longitudinal cross-relaxation rates in CW ROESY is illustrated in Figure 1. Hartmann–Hahn transfer along the diagonal cannot be avoided in any ROESY experiment. Hartmann–Hahn transfer along the antidiagonal is a more serious drawback, which can be overcome in more sophisticated ROESY experiments. The offset dependence of the net cross-relaxation rate σ_{net} requires offset corrections to be applied if quantitative information is to be extracted from ROESY spectra.

Therefore, separation of coherent J transfer (TOCSY) and transfer via cross relaxation is an important goal in the development of multiple pulse sequences used in these experiments. In this article, we give a summary of theoretical tools used to analyze the performance of multiple pulse sequences in this respect. We discuss approaches to obtain cross-relaxation-free TOCSY spectra and suppression of coherent transfer and longitudinal cross relaxation in ROESY spectra. Relations between J transfer, cross relaxation, and chemical exchange for molecules of different sizes are collected in Table 1 (since cross-relaxation rates are strongly

Figure 1 Simulation of the offset dependences of the weights of transverse (a) and longitudinal (b) cross relaxation and Hartmann–Hahn transfer (c) in CW ROESY.¹¹ In (c) the largest possible Hartmann–Hahn transfer is shown as a contour plot

Table 1 Relations between J Transfer, Cross Relaxation, and Chemical Exchange

TOCSY		NOESY	ROESY	EXSY
(a) Large Molecules ($\omega\tau_c \gg 1$)				
J transfer		Zero for weakly coupled spins; optimally suppressed for strongly coupled spins	Suppression of J transfer and of longitudinal cross relaxation are conflicting goals	Good suppression of J transfer and both types of cross relaxation necessary and possible
Cross relaxation	Zero (clean TOCSY)	σ_{NOE}		
Exchange	Fully operative	Fully operative	Fully operative	
(b) Medium Sized Molecules ($\omega\tau_c \approx 1$)				
J transfer		Zero for weakly coupled spins; optimally suppressed for strongly coupled spins	Suppression of J transfer and maximization of transverse cross relaxation are conflicting goals	Application of NOESY yields complete suppression of cross relaxation and J transfer
Cross relaxation	Reduced transverse cross relaxation cannot be suppressed	Not applicable, since $\sigma_{\text{NOE}} = 0$		
Exchange	Fully operative	Fully operative	Fully operative	
(c) Small Molecules ($\omega\tau_c \ll 1$)				
J transfer		Zero for weakly coupled spins; optimally suppressed for strongly coupled spins	Suppression of J transfer has priority since longitudinal and transverse cross relaxation have the same sign	Application of NOESY suppresses J transfer in weakly coupled spin systems; cross relaxation cannot be suppressed
Cross relaxation	Small cross-relaxation rates do not compete efficiently	σ_{NOE}		
Exchange	Fully operative	Fully operative	Fully operative	

dependent on molecular weight, the possibility of separating cross relaxation from the other interactions is considered separately for small, medium sized, and large molecules). It is obvious from this table that for molecules of any size, longitudinal cross relaxation (NOE) can be observed without contributions from ROE or J transfer. Suppression of cross relaxation in TOCSY spectra is a problem for large molecules only. Suppression of TOCSY in ROESY spectra is necessary for molecules of any size. Chemical exchange cannot be suppressed in any experiment, but can be identified by its sign in ROESY spectra.

2 THEORY

2.1 Average Hamiltonian Theory

An arbitrary multiple pulse sequence can be represented formally by a time-dependent Hamiltonian $\hat{H}(t)$. $\hat{H}(t)$ can generally be represented by a series of constant Hamiltonians that act for finite intervals of time. Each Hamiltonian introduces a unitary transformation of the density matrix that is given by its propagator, and the overall effect of the multiple pulse sequence is given by the product of these propagators. Since the product of unitary transformations is again a unitary

transformation, the product of propagators can always be written as a single propagator. The Hamiltonian corresponding to this propagator is called the effective Hamiltonian $\hat{H}_{\text{eff}}$ of the multiple pulse sequence. Average Hamiltonian theory^{4–6} yields criteria indicating whether the effective Hamiltonian can be expressed as an ‘average Hamiltonian’ and whether the effective and the average Hamiltonian are the same. It also shows how the average Hamiltonian for a given $\hat{H}(t)$ can be obtained. Average Hamiltonian theory is most useful if $\hat{H}(t)$ fulfills two conditions:

1. $\hat{H}(t)$ is periodic with a cycle time τ_{cyc} , i.e., $\hat{H}(t + n\tau_{\text{cyc}}) = \hat{H}(t)$;
2. the state of the spin system is only sampled at times $n\tau_{\text{cyc}}$. These conditions are generally fulfilled for multiple pulse sequences used for TOCSY and ROESY. $\hat{H}(t)$ is time-dependent during each cycle of the multiple pulse sequence, and the state of the spin system is interrogated only at multiples of the cycle times, i.e., at the end of the mixing time.

To apply average Hamiltonian theory to an arbitrary multiple pulse sequence, we first note that $\hat{H}(t)$ can be decomposed into a constant part $\hat{H}^0$, the Hamiltonian of the spin system in the absence of any rf irradiation, and a time-dependent part $\hat{H}^1(t)$, which describes the action of the multiple pulse sequence:

$$\hat{H}(t) = \hat{H}^0 + \hat{H}^1(t), \quad \hat{U}(t) = T \exp \left\{ -i \int_0^t [\hat{H}^0 + \hat{H}^1(t')] dt' \right\} \quad (1)$$

The propagator $\hat{U}(t)$ has been expressed as a time integral, as a generalization of the product of two propagators. The Dyson time-ordering operator^{7,8} T formally expresses the fact that in the operator product, factors with different time arguments must be arranged in order of decreasing time from left to right. The propagator $\hat{U}^1(t)$ of $\hat{\mathcal{H}}^1(t)$ takes the form

$$\hat{U}^1(t) = T \exp \left[-i \int_0^t \hat{\mathcal{H}}^1(t') dt' \right] \quad (2)$$

Multiple pulse sequences with the property $\hat{U}^1(t) = 1$ for multiples of the cycle time ($t = n\tau_{\text{cyc}}$) are called cyclic sequences. By definition, such sequences leave the state of the spin system unchanged after completion of a cycle. For such sequences and times $t = n\tau_{\text{cyc}}$, it is a good approach to try to split $\hat{U}(t)$ into a product of two terms:

$$\hat{U}(\tau_{\text{cyc}}) = \hat{U}^1(\tau_{\text{cyc}}) \hat{\hat{U}}(\tau_{\text{cyc}}) \quad (3)$$

By definition of cyclic sequences ($\hat{U}^1(\tau_{\text{cyc}}) = 1$), $\hat{\hat{U}}(\tau_{\text{cyc}})$ alone describes the time evolution of the spin system for times $t = n\tau_{\text{cyc}}$. $\hat{\hat{U}}(\tau_{\text{cyc}})$ is the propagator of the toggling-frame Hamiltonian $\hat{\hat{\mathcal{H}}}(t)$, which is defined by transforming $\hat{\mathcal{H}}^0$ into the time-dependent coordinate system defined by the action of $\hat{\mathcal{H}}^1(t)$:

$$\hat{\hat{\mathcal{H}}}(t) = [\hat{U}^1(t)^{-1}] \hat{\mathcal{H}}^0 \hat{U}^1(t) \quad (4)$$

Looking at the time evolution of a density matrix $\hat{\sigma}(t)$, we see that this definition of $\hat{\hat{\mathcal{H}}}(t)$ indeed yields a simplified description.⁵ $\hat{\sigma}(t)$ can be expressed as

$$\hat{\sigma}(t) = \hat{U}^1(t) \hat{\sigma}(0) [\hat{U}^1(t)]^{-1} \quad (5)$$

Differentiation yields [note equation (2) and $\dot{\hat{U}}^1(t) = -i\hat{\mathcal{H}}^1(t)\hat{U}^1(t)$]:

$$\begin{aligned} &= \dot{\hat{U}}^1(t) \hat{\sigma}(t) [\hat{U}^1(t)]^{-1} + \hat{U}^1(t) \dot{\hat{\sigma}}(t) [\hat{U}^1(t)]^{-1} \\ &\quad + \hat{U}^1(t) \hat{\sigma}(t) [\dot{[\hat{U}^1(t)]^{-1}}] \\ &= -i\hat{\mathcal{H}}^1(t) \hat{U}^1(t) \hat{\sigma}(t) [\hat{U}^1(t)]^{-1} + \hat{U}^1(t) \dot{\hat{\sigma}}(t) [\hat{U}^1(t)]^{-1} \\ &\quad + i\hat{U}^1(t) \hat{\sigma}(t) [\hat{U}^1(t)]^{-1} \hat{\mathcal{H}}^1(t) \\ &= -i[\hat{\mathcal{H}}^1(t), \hat{U}^1(t) \hat{\sigma}(t) [\hat{U}^1(t)]^{-1}] + \hat{U}^1(t) \dot{\hat{\sigma}}(t) [\hat{U}^1(t)]^{-1} \end{aligned} \quad (6)$$

Inserting the definition of $\hat{\hat{\mathcal{H}}}(t)$ [equation (1)] and equation (5) into the Liouville–von Neumann equation, we obtain for $\dot{\hat{\sigma}}(t)$

$$\dot{\hat{\sigma}} = -i[\hat{\mathcal{H}}^0 + \hat{\mathcal{H}}^1(t), \hat{U}^1(t) \hat{\sigma}(t) [\hat{U}^1(t)]^{-1}] \quad (7)$$

Equating equation (6) and equation (7), the commutators involving $\hat{\mathcal{H}}^1(t)$ cancel, and we obtain,

$$\hat{U}^1(t) \dot{\hat{\sigma}}(t) [\hat{U}^1(t)]^{-1} = -i[\hat{\mathcal{H}}^0, \hat{U}^1(t) \hat{\sigma}(t) [\hat{U}^1(t)]^{-1}] \quad (8)$$

Multiplying this equation by $[\hat{U}^1(t)]^{-1}$ from the left and by $\hat{U}^1(t)$ from the right yields

$$\begin{aligned} \dot{\hat{\sigma}}(t) &= -i[[\hat{U}^1(t)]^{-1} \hat{\mathcal{H}}^0 \hat{U}^1(t) \hat{\sigma}(t) - \hat{\sigma}(t) [\hat{U}^1(t)]^{-1} \hat{\mathcal{H}}^0 \hat{U}^1(t)] \\ &= -i[[\hat{U}^1(t)]^{-1} \hat{\mathcal{H}}^0 \hat{U}^1(t), \hat{\sigma}(t)] = -i[\hat{\hat{\mathcal{H}}}^0(t), \hat{\sigma}(t)] \end{aligned} \quad (9)$$

The formal solution of this equation is [note that $(0) = \hat{\sigma}(0)$]

$$\hat{\sigma}(t) = \hat{\hat{U}}(t) \hat{\sigma}(0) [\hat{\hat{U}}(t)]^{-1} = \hat{\hat{U}}(t) \hat{\sigma}(0) [\hat{\hat{U}}(t)]^{-1} \quad (10)$$

where

$$\hat{\hat{U}}(t) = T \exp \left[-i \int_0^t \hat{\hat{\mathcal{H}}}^0(t') dt' \right] = \exp(-i\hat{\mathcal{H}}_{\text{eff}}^0 t) \quad (11)$$

Inserting equation (10) into equation (5), we see that the propagator given in equation (3) is a valid decomposition of $\hat{U}(t)$.

As has been mentioned, $\hat{\hat{U}}(\tau_{\text{cyc}})$ yields a complete description of the time evolution of the spin system under cyclic sequences. $\hat{\mathcal{H}}_{\text{eff}}$ is the effective Hamiltonian. In general, the effective Hamiltonian has the form

$$\hat{\mathcal{H}}_{\text{eff}} = \hat{\mathcal{H}}_{\text{eff}}^{\text{lin}} + \hat{\mathcal{H}}_{\text{eff}}^{\text{bil}} + \hat{O}(\geq 3) \quad (12)$$

The terms that are linear in spin operators are collected in $\hat{\mathcal{H}}_{\text{eff}}^{\text{lin}}$.

$$\hat{\mathcal{H}}_{\text{eff}}^{\text{lin}} = \sum_k \sum_{\mu} c_{k\mu} \hat{I}_{k\mu} \quad (13)$$

with $\mu = x, y$, or z . With the help of the coefficients $c_{k\mu}$, the effective offset of spin k may be defined as

$$\Omega_k^{\text{eff}} = \sqrt{\sum_{\mu} |c_{k\mu}|^2} \quad (14)$$

Terms that are bilinear in spin operators are summarized in $\hat{\mathcal{H}}_{\text{eff}}^{\text{bil}}$, which may be used to define effective coupling constants J_{kl}^{eff} . All terms that contain products of three or more spin operators are represented in Equation (12) by $\hat{O}(\geq 3)$.

$\hat{\mathcal{H}}_{\text{eff}}$ can be expanded with the help of the Magnus expansion.^{5,9} The zeroth-order term in the Magnus expansion is the average Hamiltonian $\bar{\hat{\mathcal{H}}}$, which is given by

$$\bar{\hat{\mathcal{H}}} = \frac{1}{\tau_{\text{cyc}}} \int_0^{\tau_{\text{cyc}}} \hat{\hat{\mathcal{H}}}^0(t') dt' \quad (15)$$

2.2 Hartmann–Hahn Transfer

Let us consider a system of two coupled spins $\frac{1}{2}$. The Hamiltonian for this system can be written as a sum of the Zeeman part $\hat{\mathcal{H}}_Z$ and a coupling part $\hat{\mathcal{H}}_J$:

$$\begin{aligned}\hat{\mathcal{H}}_0 &= \hat{\mathcal{H}}_Z + \hat{\mathcal{H}}_J \\ &= \Omega_1 \hat{I}_{1z} + \Omega_2 \hat{I}_{2z} + 2\pi J (\hat{I}_{1x} \hat{I}_{2x} + \hat{I}_{1y} \hat{I}_{2y} + \hat{I}_{1z} \hat{I}_{2z})\end{aligned}\quad (16)$$

Assuming the spin system to be prepared at $t = 0$ with spin 1 polarized along z and spin 2 saturated, the initial density operator can be represented as $\hat{\rho}(0) = \hat{I}_{1z}$. For the analysis of Hartmann–Hahn transfer, it is more convenient to decompose $\hat{\mathcal{H}}_0$ into the terms $\hat{\mathcal{H}}'_0$ and $\hat{\mathcal{H}}''_0$:

$$\hat{\mathcal{H}}'_0 = (\Omega_1 - \Omega_2) \frac{\hat{I}_{1z} - \hat{I}_{2z}}{2} + 2\pi J (\hat{I}_{1x} \hat{I}_{2x} + \hat{I}_{1y} \hat{I}_{2y}) \quad (17a)$$

$$\hat{\mathcal{H}}''_0 = (\Omega_1 + \Omega_2) \frac{\hat{I}_{1z} + \hat{I}_{2z}}{2} + 2\pi J \hat{I}_{1z} \hat{I}_{2z} \quad (17b)$$

$\hat{\mathcal{H}}''_0$ does not influence the time evolution of the density operator, and can be ignored, since it commutes with both $\hat{\mathcal{H}}'_0$ and $\hat{\rho}(0) = \hat{I}_{1z}$.

The evolution of $\hat{\rho}(t)$ due to the remaining operator $\hat{\mathcal{H}}'_0$ is strongly dependent on the ratio of the coupling constant J with the difference $\Delta\Omega = (\Omega_1 - \Omega_2)$. The evolution of $\hat{\rho}(t)$ is presented in Figure 2 with numerical simulations for the cases $|\Delta\Omega| \gg |2\pi J_{12}|$ [(a): weak coupling limit], $|\Delta\Omega| \approx |2\pi J_{12}|$ [(b): strong coupling], and $|\Delta\Omega| \ll |2\pi J_{12}|$ [(c): Hartmann–Hahn limit].

In the weak coupling limit (Figure 2a), the density operator of the spin system does not evolve, so the polarization of spin 1 is invariant.

In the case of strong coupling (Figure 2b), the density operator evolves in an oscillatory manner. Starting from $\hat{\rho}(0) = \hat{I}_{1z}$, terms $\hat{I}_{2z}$ as well as $\hat{I}_{1y}\hat{I}_{2x} - \hat{I}_{1x}\hat{I}_{2y}$ and $\hat{I}_{1x}\hat{I}_{2x}$

+ $\hat{I}_{1y}\hat{I}_{2y}$ are created periodically. Thus, a part of the initial polarization of spin 1 ($\hat{I}_{1z}$) is periodically transferred to spin 2 ($\hat{I}_{2z}$).

In the Hartmann–Hahn limit (Figure 2c), only the terms $\hat{I}_{2z}$ and $\hat{I}_{1y}\hat{I}_{2x} - \hat{I}_{1x}\hat{I}_{2y}$ are formed, starting from $\hat{\rho}(0) = \hat{I}_{1z}$. The characteristic property of this limiting case is the complete transfer of polarization between the coupled spins after a time $1/2J$.

In the general case, the rate and maximum efficiency of transfer via scalar coupling in multiple pulse sequences is a complicated function of the exact sequence.^{10,11} Such cases can be described using effective offsets $\Omega_{\text{eff},1}$ and $\Omega_{\text{eff},2}$ as well as an effective coupling constant J_{12}^{eff} (cf. equations (12)–(14)). Fulfillment of the Hartmann–Hahn condition $|\Delta\Omega| \ll |2\pi J_{12}|$ is a necessary condition for the occurrence of Hartmann–Hahn transfer between two spins. Under the influence of a multiple pulse sequence, the Hartmann–Hahn condition takes the form $|\Delta\Omega_{\text{eff}}| \ll |2\pi J_{12}^{\text{eff}}|$. For spins that have similar chemical shift, corresponding to cross peaks along the diagonal of a 2D spectrum, $\Delta\Omega_{\text{eff}}$ can be expressed as $\Delta\Omega_{\text{eff}} = (\Delta\Omega_{\text{eff}}/\Delta\Omega) \Delta\Omega \approx (\partial\Omega_{\text{eff}}/\partial\Omega) \Delta\Omega = \lambda \Delta\Omega$. Thus, the slope λ of Ω_{eff} as a function of Ω gives a measure for the occurrence of Hartmann–Hahn transfer near the diagonal. λ is identical to the scaling factor introduced by Waugh¹² in the context of heteronuclear decoupling.

2.3 Invariant Trajectory Approach

Consider an uncoupled spin k subject to the action of an arbitrary multiple pulse sequence consisting of a

Figure 2 Time evolution of the initial density operator $\hat{\rho}(0) = \hat{I}_{1z}$ in a two-spin system with a coupling of 10 Hz under the influence of the Hamiltonian $\hat{\mathcal{H}}_0$. Curves from top to bottom show the expectation values of $\hat{I}_{1z}$, $\hat{I}_{2z}$, $\hat{I}_{1y}\hat{I}_{2x} - \hat{I}_{1x}\hat{I}_{2y} = \langle ZQ \rangle_y$ and $\hat{I}_{1x}\hat{I}_{2x} + \hat{I}_{1y}\hat{I}_{2y} = \langle ZQ \rangle_x$. (a) In the weak coupling limit ($|\Delta\nu| = 1000 \text{ Hz} \gg |J_{12}|$), the polarization of $\hat{I}_{1z}$ is invariant. (b) In the case of strong coupling ($|\Delta\nu| = 10 \text{ Hz} = |J_{12}|$), the polarization $\hat{I}_{1z}$ is partly transferred to $\hat{I}_{2z}$. (c) In the Hartmann–Hahn limit ($|\Delta\nu| = 0 \text{ Hz} \ll |J_{12}|$), transfer of $\hat{I}_{1z}$ to $\hat{I}_{2z}$ is complete for odd multiples of $1/2J$.

basic sequence that is repeated during the mixing time of an experiment. The trajectory followed by a magnetization vector during the basic sequence is called invariant¹³ if the orientations of the vector at the beginning and end of the basic sequence are the same. By definition, magnetization that moves on this trajectory does not experience a net rotation during a complete basic sequence. All other magnetization components experience a net rotation after each basic sequence, and are dephased by rf inhomogeneity during the repetitions of the basic sequence. The extent of dephasing depends on the effective field produced by the multiple pulse sequence, the mixing time, and the rf inhomogeneity of the probe. In this case, only the behavior of magnetization moving on the invariant trajectory need be considered in order to understand the properties of the multiple pulse sequence. The method of invariant trajectories allows an easy calculation of the effective cross relaxation rate σ_{eff} that is active during a multiple pulse sequence. For a pair of spins with identical offsets, σ_{eff} is given by

$$\sigma_{\text{eff}} = w_l \sigma_{\text{NOE}} + w_t \sigma_{\text{ROE}} \quad (18)$$

where the weights w_l and w_t of longitudinal and transverse cross relaxation are given by the average squared longitudinal and transverse components of the invariant trajectory:¹³

$$\begin{aligned} w_l &= \frac{1}{\tau_{\text{cyc}}} \int_0^{\tau_{\text{cyc}}} n_{0,z}^2(t) dt = \langle n_{0,z}^2 \rangle \\ w_t &= \frac{1}{\tau_{\text{cyc}}} \int_0^{\tau_{\text{cyc}}} (n_{0,x} + n_{0,y})^2(t) dt = \langle n_{0,(x,y)}^2 \rangle \end{aligned} \quad (19)$$

Thus, the effective cross relaxation during a multiple pulse sequence is a linear combination of the longitudinal and

transverse cross relaxation rates σ_{NOE} and σ_{ROE} , which are properties of the sample, with the weights $w_l(\Omega)$ and $w_t(\Omega)$, which are properties of the sequence. As an example, invariant trajectories of the phase-alternating ROESY sequence $(\pi_x \pi_{-x})_n$ for two offsets are shown in Figure 3. From the x , y , and z components of the invariant trajectories of this sequence (top of Figure 3), the weights of longitudinal and transverse cross relaxation can be obtained (bottom).

2.4 Connection between the Invariant Trajectory Approach and AHT

For basic sequences that create a nonzero effective field $B_{\text{eff},k}$ (spin lock sequences), the orientation of the invariant trajectory is given by the orientation of $B_{\text{eff},k}$.

However, there is also a more fundamental connection between invariant trajectories and effective fields. In the following discussion, we shall show that for any multiple pulse sequence, there is a relationship between the time-averaged z component of the invariant trajectory $\langle n_{0,z} \rangle$ and the slope λ of the effective field as a function of the offset.¹⁴ This result is central to the development of ROESY sequences, since the weight of longitudinal cross relaxation is proportional to $\langle n_{0,z}^2 \rangle$, while λ is a measure for the occurrence of Hartmann–Hahn transfer along the diagonal of the 2D spectrum.

In order to calculate $\lambda = \partial \Omega_{\text{eff}} / \partial \Omega$ as the limit $\lim_{\Delta \Omega \rightarrow 0} \Delta \Omega_{\text{eff}} / \Delta \Omega = \lim_{\Delta \Omega \rightarrow 0} (\Omega_{\text{eff}} - \Omega'_{\text{eff}}) / \Delta \Omega$, the effective propagator $\hat{U}(\tau_{\text{cyc}})$ after one cycle of duration τ_{cyc} of a repetitive multiple pulse sequence is calculated:

Figure 3 Invariant trajectories for the sequence $(\pi_x \pi_{-x})_n$ for an on-resonant spin (solid lines) and for an off-resonant spin with offset $\Omega = \gamma B_1$ (dashed lines). The x , y , and z components, together with the squares of the longitudinal and transverse components, are shown. For off-resonant spins, the sequence locks in the (y,z) plane. The weights w_t and w_l of transverse and longitudinal cross relaxation are calculated as the average square transverse and average square longitudinal components of the invariant trajectories. For the on-resonant spin, $\langle n_x^2 + n_y^2 \rangle = \langle n_z^2 \rangle = 0.5$, and for the off-resonant spin, $w_t = \langle n_x^2 + n_y^2 \rangle = 0.88$ and $w_l = \langle n_z^2 \rangle = 0.12$

$$\begin{aligned}\hat{U}(\tau_{\text{cyc}}) &= \prod_j \hat{U}_j = \prod_j \exp(-i\hat{\mathcal{H}}_j \tau_j) = \exp(-i\hat{\mathcal{H}}_{\text{eff}} \tau_{\text{cyc}}) \\ &= \exp[-i\Omega_{\text{eff}} \tau_{\text{cyc}} \hat{I}_0(0)]\end{aligned}\quad (20)$$

$\hat{U}(\tau_{\text{cyc}})$ is given by the time-ordered product of individual pulse propagators $\hat{U}_j$, which represent the propagators for individual pulses of duration τ_j and Hamiltonian $\hat{\mathcal{H}}_j$. $\hat{\mathcal{H}}_{\text{eff}}$ is the effective Hamiltonian for one cycle. For a system consisting of a single spin- $\frac{1}{2}$, the effective Hamiltonian $\hat{\mathcal{H}}_{\text{eff}}$ may be written as $\Omega_{\text{eff}} \hat{I}_0(0)$, where Ω_{eff} is the effective chemical shift and $\hat{I}_0(0)$ defines the invariant trajectory¹³ at time $t = 0$:

$$\hat{\mathcal{H}}_{\text{eff}} = \Omega_{\text{eff}} \hat{I}_0(0) \quad (21)$$

To calculate the effective chemical shift Ω'_{eff} at the offset $\Omega' = \Omega + \Delta\Omega$, the $\hat{\mathcal{H}}_j$ are modified by $\hat{\mathcal{H}}_1 = \Delta\Omega \hat{I}_z$: $\hat{\mathcal{H}}'_j = \hat{\mathcal{H}}_j + \hat{\mathcal{H}}_1 = \hat{\mathcal{H}}_j + \Delta\Omega \hat{I}_z$. The resulting propagator,

$$\hat{U}'(\tau_{\text{cyc}}) = \exp(-i\hat{\mathcal{H}}'_{\text{eff}} \tau_{\text{cyc}}) = \exp[-i\Omega'_{\text{eff}} \tau_{\text{cyc}} \hat{I}_0(0)] \quad (22)$$

may be divided into two factors:^{4,5}

$$\hat{U}'(\tau_{\text{cyc}}) = \hat{U}(\tau_{\text{cyc}}) \hat{U}_1(\tau_{\text{cyc}}) \quad (23)$$

with

$$\hat{U}_1(\tau_{\text{cyc}}) = \exp(-i\hat{\mathcal{H}}_{1,\text{eff}} \tau_{\text{cyc}}) = T \exp \left\{ -i \left[\int_0^{\tau_{\text{cyc}}} \hat{\mathcal{H}}_1(t) dt \right] \right\} \quad (24)$$

where the toggling frame Hamiltonian is given by $\hat{\mathcal{H}}_1(t) = \hat{U}^{-1}(t) \Delta\Omega \hat{I}_z \hat{U}(t)$. In zeroth-order average Hamiltonian theory, equation (24) simplifies to

$$\hat{U}_1(\tau_{\text{cyc}}) = \exp(-i\hat{\mathcal{H}}_{\text{eff},1} \tau_{\text{cyc}}) = \exp \left\{ -i \left[\int_0^{\tau_{\text{cyc}}} \hat{\mathcal{H}}_1(t) dt \right] \right\} \quad (25)$$

This simplification is justified in the limit $\Delta\Omega \rightarrow 0$. Expansion of $\hat{U}'(\tau_{\text{cyc}})$, equation (23), according to the Baker–Campbell–Hausdorff formula to first order yields

$$\hat{U}'(\tau_{\text{cyc}}) = \exp\{-i(\hat{\mathcal{H}}_{\text{eff}} \tau_{\text{cyc}} + \hat{\mathcal{H}}_{\text{eff},1} \tau_{\text{cyc}}) - \frac{1}{2}[\hat{\mathcal{H}}_{\text{eff}}, \hat{\mathcal{H}}_{\text{eff},1}] \tau_{\text{cyc}}^2\} \quad (26)$$

Comparing equations (22) and (26), we find

$$\hat{\mathcal{H}}'_{\text{eff}} = \Omega'_{\text{eff}} \hat{I}_0(0) = (\hat{\mathcal{H}}_{\text{eff}} + \hat{\mathcal{H}}_{\text{eff},1}) - \frac{1}{2}[\hat{\mathcal{H}}_{\text{eff}}, \hat{\mathcal{H}}_{\text{eff},1}] \tau_{\text{cyc}} \quad (27a)$$

$$\begin{aligned}&= \Omega_{\text{eff}} \hat{I}_0(0) + \Omega_{\text{eff},1} \hat{I}_1(0) \\ &\quad - \frac{1}{2}i\Omega_{\text{eff}}\Omega_{\text{eff},1}[\hat{I}_0(0), \hat{I}_1(0)]\tau_{\text{cyc}}\end{aligned}\quad (27b)$$

where $\hat{I}_1(0)$ is defined as $\hat{\mathcal{H}}_{\text{eff},1}/\Omega_{\text{eff},1}$.

For $\Delta\Omega \ll \Omega_{\text{eff}}$ and $\Delta\Omega \tau_{\text{cyc}} \ll 1$, only terms parallel to $\hat{I}_0(0)$ contribute to the magnitude of the effective field Ω'_{eff} at offset Ω' . Since the commutator $[\hat{I}_0(0), \hat{I}_1(0)]$ is perpendicular to $\hat{I}_0(0)$, the last term in equation (27b) may be neglected. To find the contribution of the second term of equation (27b), we calculate the projection of $\Omega_{\text{eff},1} \hat{I}_1(0)$ onto the direction of $\hat{I}_0(0)$. This is given by $\Omega_{\text{eff},1} \text{Tr} \{ \hat{I}_0(0) \hat{I}_1(0) \}$. Thus, the magnitude of the effective field Ω'_{eff} at offset Ω' is given by

$$\Omega'_{\text{eff}} = \Omega_{\text{eff}} + \Omega_{\text{eff},1} \text{Tr} \{ \hat{I}_0(0) \hat{I}_1(0) \} \quad (28)$$

For $\Delta\Omega \rightarrow 0$, the slope λ can be expressed as

$$\lambda = \frac{\Omega'_{\text{eff}} - \Omega_{\text{eff}}}{\Delta\Omega} = \frac{\Omega_{\text{eff},1}}{\Delta\Omega} \text{Tr} \{ \hat{I}_0(0) \hat{I}_1(0) \} \quad (29)$$

According to equation (25), $\Omega_{\text{eff},1} \hat{I}_1(0) = \hat{\mathcal{H}}_{\text{eff},1}$ is given by

$$\begin{aligned}\Omega_{\text{eff},1} \hat{I}_1(0) &= \frac{1}{\tau_{\text{cyc}}} \int_0^{\tau_{\text{cyc}}} \hat{\mathcal{H}}_1(t) dt \\ &= \frac{1}{\tau_{\text{cyc}}} \int_0^{\tau_{\text{cyc}}} \hat{U}^{-1}(t) \Delta\Omega \hat{I}_z \hat{U}(t) dt\end{aligned}\quad (30)$$

Inserting equation (30) into equation (29), we find

$$\begin{aligned}\lambda &= \frac{1}{\tau_{\text{cyc}}} \text{Tr} \left\{ \hat{I}_0(0) \int_0^{\tau_{\text{cyc}}} \hat{U}^{-1}(t) \hat{I}_z \hat{U}(t) dt \right\} \\ &= \frac{1}{\tau_{\text{cyc}}} \int_0^{\tau_{\text{cyc}}} \text{Tr} \{ \hat{I}_0(0) \hat{U}^{-1}(t) \hat{I}_z \hat{U}(t) \} dt \\ &= \frac{1}{\tau_{\text{cyc}}} \int_0^{\tau_{\text{cyc}}} \text{Tr} \{ \hat{U}(t) \hat{I}_0(0) \hat{U}^{-1}(t) \hat{I}_z \} dt \\ &= \frac{1}{\tau_{\text{cyc}}} \int_0^{\tau_{\text{cyc}}} \text{Tr} \{ \hat{I}_0(t) \hat{I}_z \} dt \\ &= \frac{1}{\tau_{\text{cyc}}} \int_0^{\tau_{\text{cyc}}} n_{0,z}(t) dt = \langle n_{0,z} \rangle\end{aligned}\quad (31)$$

where $n_{0,z}(t)$ is the z component of the invariant trajectory $\hat{I}_0(t)$. The general result of equation (31) can be stated as follows: the slope of Ω_{eff} with respect to Ω is identical to the average z component of the invariant trajectory. Equation (28) relates the parameter λ central to the theory of spin decoupling to the invariant trajectory approach. We shall return to this result in Section 3.2.

3 SEPARATION OF HARTMANN–HAHN TRANSFER AND CROSS RELAXATION

3.1 Cross-Relaxation Compensated TOCSY Experiments

The TOCSY experiment is used to achieve transfer among spins in scalar-coupled spin systems. To achieve efficient TOCSY transfer, the effective fields experienced by the spins must be matched over the offset range of interest ($\lambda \ll 1$). Several multiple pulse sequences have been proposed to achieve this goal.^{1,11,15–18} During these multiple pulse sequences, longitudinal and transverse cross-relaxation rates σ_{NOE} and σ_{ROE} are active and contribute to the effective cross relaxation rate σ_{eff} with the weights w_l and w_t [equation (18)]. Since σ_{NOE} and σ_{ROE} have the same sign for small molecules, it follows that cross-relaxation contributions cannot be suppressed near the diagonal of TOCSY spectra of small molecules, since, whatever w_t and w_l might be, the terms in equation (18) will always add to yield a nonvanishing σ_{eff} . Fortunately, cross-relaxation rates of such molecules are small, so that artifacts due to cross relaxation are rarely observed in the relatively short mixing times used.

As shown in Figure 4(a), y magnetization of on-resonant spins entering the $90^\circ_x 180^\circ_y 90^\circ_x$ composite pulse of a MLEV sequence spends equal amounts of time along longitudinal and transverse directions; therefore, $w_t = w_l = \frac{1}{2}$. Since

Figure 4 (a) Invariant trajectory starting from y magnetization for the $90^\circ_x 180^\circ_y 90^\circ_x$ composite pulse of the MLEV sequence for on-resonant irradiation. In (b) and (c), the offset dependence of the effective cross-relaxation rate σ_{eff} is shown in units of σ_{eff} in the spin diffusion limit. On-resonance, longitudinal and transverse cross relaxation have equal weights ($w_l = w_t = \frac{1}{2}$). Therefore, a net cross-relaxation rate of $\frac{1}{4}\sigma_{\text{ROE}}$ is observed for two on-resonant spins during this sequence for a molecule in the spin diffusion limit (b). Introduction of delays of length $\Delta = \tau_{90}$ in CLEAN MLEV,¹⁹ $90^\circ_x \Delta 180^\circ_y \Delta 90^\circ_x$, results in suppression of cross relaxation on-resonance (c)

$\sigma_{\text{NOE}} = 0$ for medium sized molecules, a cross relaxation contribution $\frac{1}{2}\sigma_{\text{ROE}}$ results for TOCSY spectra obtained with this mixing sequence. This contribution cannot be suppressed, since this would require $w_t = 0$, which cannot be realized for any multiple pulse sequence. In the case of large molecules ($\sigma_{\text{ROE}}/\sigma_{\text{NOE}} = -2$), cross-relaxation rates are large, and cross relaxation can therefore compete with TOCSY transfer, leading to artifacts. It follows from equation (19) that for $w_t \approx w_1$, the contribution $w_1\sigma_{\text{ROE}}$ of transverse cross relaxation outweighs $w_1\sigma_{\text{NOE}}$, and a residual ROE contribution is therefore observed in TOCSY spectra of large molecules. The net cross-relaxation rate of this sequence for molecules in the spin diffusion limit is displayed in Figure 4(b) in units of σ_{ROE} . On resonance, ROESY cross peaks of one-quarter maximum intensity are expected to appear. From the invariant trajectory of the $90^\circ_x 180^\circ_y 90^\circ_x$ composite pulse (Figure 4a), there follows a straightforward way to eliminate this contribution for large molecules. If delays of appropriate duration ($\Delta = \tau_{90}$ for $\sigma_{\text{ROE}}/\sigma_{\text{NOE}} = -2$) are introduced into the MLEV scheme at positions where the magnetization is longitudinal, w_t and w_1 can be modified such that ROE and NOE contributions cancel each other. Figure 4(c) shows the offset dependence of the cross-relaxation rate in the so-called CLEAN TOCSY experiment¹⁹ obtained in this way. Cross relaxation is completely suppressed on-resonance in this experiment, while residual ROE contributions remain along the diagonal of the 2D spectrum.

While the introduction of delays is the most straightforward approach to suppress cross relaxation, and has been used frequently,^{19,20} it suffers from an increase in the rf power dissipated in the sample (at constant average field strength $\gamma\bar{B}_1$), since the introduction of delays into any multiple pulse sequence lowers the duty ratio. This undesired effect is alleviated in more modern approaches to obtain cross relaxation compensated TOCSY mixing sequences. These approaches make use of crafted pulses to achieve a proper weighting of NOE and ROE during the multiple pulse sequence. Either the individual pulses of an existing TOCSY sequence are replaced by shaped pulses,²¹ or TOCSY mixing sequences are optimized from scratch with the required weighting of NOE and ROE as a constraint,^{22–24} resulting in sequences such as CITY²² and TOWNY.²³ An example of a cross-relaxation compensated TOCSY spectrum, obtained using a MLEV mixing sequence consisting of shaped 90° pulses, is displayed in Figure 5.

An alternative approach to separate Hartmann–Hahn transfer and ROE was suggested by Ravikumar and Bothner-By.²⁵ It relies on the characteristic time evolution of coherent and incoherent magnetization transfer. However, the separation remains incomplete, since cross relaxation and coherent transfer both contain zero-frequency contributions.

3.2 Suppression of Hartmann–Hahn Transfer in ROESY Experiments

Using equation (31), which relates λ to $\langle n_{0,z} \rangle$, a relation between λ and the weight of longitudinal cross relaxation $w_1 = \langle n_{0,z}^2 \rangle$ can be derived for cross peaks near the diagonal. As the inequality $\langle n_{0,z}^2 \rangle \geq \langle n_{0,z} \rangle^2$ always holds, it follows immediately that

$$w_1 \geq \lambda^2 \quad (32)$$

This inequality shows that the suppression of longitudinal cross relaxation ($w_1 = \min.$) and of TOCSY transfer ($\lambda = \max.$) are conflicting goals. Suppression of longitudinal cross relaxation can be achieved only if TOCSY transfer is allowed, and vice versa—or, there is no ROESY without NOESY and without TOCSY. The best a sequence can do is.

$$w_1 = \lambda^2 \quad (33)$$

This is only possible if $n_{0,z}(t)$ is constant during τ_{cyc} , as is the case in CW ROESY.^{2,26,27} The latter can be described analytically in the following way. The invariant trajectory is static and has the orientation

$$\mathbf{n}_0 = \cos\theta\mathbf{e}_z + \sin\theta\mathbf{e}_x, \quad \text{with } \tan\theta = \frac{\gamma B_1}{\Omega - \Omega_{\text{rf}}} \quad (34)$$

where γB_1 is the spin lock field strength, θ is the lock angle as measured off the z axis, and Ω_{rf} is an offset frequency of the CW irradiation. The weights for longitudinal (w_1) and transverse (w_t) cross relaxation along the diagonal are

$$w_1 = \cos^2\theta, \quad w_t = \sin^2\theta \quad (35)$$

The effective chemical shift Ω_{eff} is given by

$$\Omega_{\text{eff}} = \sqrt{(\gamma B_1)^2 + (\Omega - \Omega_{\text{rf}})^2} \quad (36)$$

and the scaling $\lambda_{\text{CW}} = \partial\Omega_{\text{eff}}/\partial\Omega$ of the chemical shift of this sequence is

$$\lambda_{\text{CW}} = \frac{\partial\Omega_{\text{eff}}}{\partial\Omega} = \frac{\Omega - \Omega_{\text{rf}}}{\sqrt{(\gamma B_1)^2 + (\Omega - \Omega_{\text{rf}})^2}} = \cos\theta = \sqrt{w_1} \quad (37)$$

Thus, CW ROESY has the best properties with respect to the simultaneous suppression of NOE and TOCSY that are possible, since equation (33) is fulfilled. For any w_t , there is no better ROESY sequence with respect to the goal of suppressing longitudinal cross relaxation and TOCSY simultaneously. In practice, a compromise must be made between the efficiency of ROESY transfer (minimization of w_1) and the degree of suppression of coherent transfer (maximization of λ). The large variation in w_1 and w_t over the spectral range in CW ROESY is a strong drawback of this sequence. From an experimental point of view, an additional requirement is that w_t be uniform over the spectral width and λ not be scaled beyond a certain degree over the spectral width. A number of approaches have been proposed to address this goal.

3.2.1 Sequences Composed of CW Irradiations

The application of a very strong spin lock field in a ROESY experiment yields a very smooth offset dependence in CW ROESY, as displayed in Figure 6(a) (left). However, the application of such strong fields is prohibitive because of serious Hartmann–Hahn transfer (Figure 6(a), right). Therefore, judicious choice of the spin lock field strength is important, as shown in Figure 6(b).²⁶ Furthermore, coherent transfer is much more dependent on the position of the rf irradiation frequency than cross relaxation. Therefore, coherent transfer can be reduced by judicious placement of the irradiation position (Figure 6c).^{26,28} However, optimal placement of the transmitter offset requires prior knowledge of the coupling networks that can lead to TOCSY transfer.

Without such prior knowledge, the transmitter offset has to be placed outside the spectral region according to equation (37) in order to avoid Hartmann–Hahn matching between any two spins. However, this results in a strong dependence of the net cross-relaxation rate on Ω , which renders the interpretation of the spectra difficult. Still, the optimal behavior of CW irradiation with respect to TOCSY suppression renders sequences employing stretches of CW irradiation attractive.

Two related approaches have been developed to deal with the stated problem. In the first, proposed by Cavanagh and Keeler,²⁹ the transmitter offset is swept through the offset

range of the spectrum as depicted in Figure 7(a). This method avoids continuous irradiation at any one frequency, and therefore avoids extended periods of Hartmann–Hahn matching. However, the offset dependence of the cross-relaxation rate of this sequence has not been published, and only qualitative interpretations of such spectra appear feasible at this time. Furthermore, the programming of the frequency sweep is rather demanding from an experimental point of view.

The second approach to modify CW ROESY to obtain ROESY spectra with suppression of TOCSY transfer—the use of JS ROESY ('jump symmetrized') sequences—makes use of

(a)

Figure 5 MLEV-17 spectra of the oxidized form of the peptide CTRPNNNTRKSIHIGPGRAFYTTGEIIGDIRQAH in DMSO at 24°C, recorded using a mean rf field strength $\gamma B_1/2\pi = 6.79$ kHz at 600 MHz. Cross peaks with the same sign as the diagonal peaks (coherent transfer) are plotted as dashed lines. Cross peaks with opposite sign (incoherent transfer) are plotted as solid lines. Only the cross-relaxation peaks are assigned. (a) In the uncompensated TOCSY experiment, strong cross peaks occur owing to cross relaxation. (b) In the TOCSY spectrum recorded using an MLEV-17 expansion of an optimized shaped 90° pulse,²¹ the cross-relaxation peaks have disappeared

Figure 6 Simulations of Hartmann–Hahn transfer (left) and net cross-relaxation rate σ_{net} (right) for a molecule in the spin diffusion limit in ROESY sequences. Application of a very strong spin lock field (a) would result in a maximal σ_{net} , but complete Hartmann–Hahn matching would make such spectra useless. Reducing the spin lock field strength (b) strongly attenuates TOCSY at the expense of a relatively moderate offset dependence of σ_{net} . TOCSY transfer along the antidiagonal, as observed in (b), is suppressed by off-resonant irradiation of the spin lock field (c). However, the offset dependence of σ_{net} is much more pronounced in this case. Alternating application of two spin lock fields at opposite ends of the spectrum in JS ROESY (b) results in very smooth offset behavior, with TOCSY still being suppressed (d). Phase-alternating ROESY sequences (Figure 7a) show similar offset behavior for cross relaxation and coherent transfer (e). It is obvious that maximal transverse cross relaxation is achieved on-resonance at the cost of complete Hartmann–Hahn matching. Simulations of TOCSY show contour plots of the largest possible Hartmann–Hahn transfer amplitude in a two-spin system. The lowest level corresponds to a transfer amplitude of 0.1; the level spacing is 0.2

only two irradiation positions placed outside the low- and high-field edges of the spectrum [Figure 7(b)]. Since the directions of the spin lock axes differ for the high-field and the low-field spin lock for all offsets (except for $\Omega = 0$), a compensating pulse has to be applied that rotates the magnetization into the new lock direction for every offset. In the pulse sequence of JS ROESY shown in Figure 7(b), this is achieved by the pair of 180° pulses between the two off-resonant spin locks. The field strength of these pulses is related to the spin lock field strength and to the on-resonance lock angle θ .¹⁴ The averaging of the offset dependences of the two stretches of CW irradiation results in a very smooth offset behavior and good suppression of Hartmann–Hahn transfer, as shown in Figure 6(d). Close to on-resonance, this sequence achieves optimal suppression of TOCSY, since λ does not differ from the optimum value

[given by equation (37)] at any time. Further off-resonance, the performance of the sequence is reduced, since the λ value for a given offset may differ grossly for high-field and low-field CW irradiation, and must not be averaged between the extended stretches of CW irradiation. The smaller of the two λ values (of the low- and high-field irradiations) gives a measure of the occurrence of TOCSY.

3.2.2 $\pi_x\pi_{-x}$ ROESY

A second approach to obtain ROESY spectra with suppression of TOCSY transfer is the use of multiple pulse sequences optimized for this goal. Only one group of sequences has so far been proposed.^{30,31} These consist of a series of phase-alternating 180° pulses $(\pi_x\pi_{-x})_n$ (Figure 8), where

Figure 7 CW ROESY sequences with off-resonant irradiation spin locks. For each experiment, the pulse sequence (upper trace) and the position of the spin lock irradiation (lower trace) are given. (a) In the frequency swept variant,²⁹ the irradiation frequency is moved from the middle of the spectral region to the low-field edge, to the high-field edge, and back to the middle. (b) In the JS ROESY experiment, the mixing time consists of periods of low-field and high-field irradiation with a pair of 180° pulses mediating between the spin locks. The offset of the spin locks is generated by superimposing a phase gradient over a CW spin lock

Figure 8 ROESY sequences employing spin locks consisting of phase-alternating pulses.^{30,31} The original sequence (a) can be modified by the use of shaped pulses (b) or by the introduction of delays (c) to increase the weight of transverse cross relaxation

Figure 9 Simulations of the offset behavior of cross relaxation of JS ROESY and a ROESY employing a phase-alternating spin lock ($\pi_x^{3L}\pi_{-x}^{3L}$)_n,³¹ with parameters chosen to yield a net cross-relaxation rate of $0.476\sigma_{\text{ROE}}$ on-resonance. For JS ROESY (a), an on-resonance lock angle $\theta_0 = 53.77^\circ$ was used. The phase-modulating sequence (b) yields the same net cross-relaxation rate using the shaped pulse described by Hwang et al.³¹ The offset dependence of cross relaxation is less pronounced in JS ROESY, making direct use of intensities feasible for distance calculations. (c) Simulations of λ as a function of Ω in the offset range $\pm 1.2/(\gamma B_1)^2$. Near on-resonance, JS ROESY suppresses TOCSY better, while the phase-alternating sequence performs better towards the edges of the spectrum

each individual 180° pulse can be rectangular (which might include delays) or shaped. Sequences using pulses with flip angles other than 180° can also be used, and have been

Figure 10 ROESY spectra of a disaccharide obtained with the ROESY sequences of Figures 7(b) (a) and Figure 8(b) (b). Positive (negative) levels are plotted as dashed (solid) lines. Both pulse sequences show similar ROE cross-peak intensities (solid contour lines). An artifact due to Hartmann–Hahn transfer between geminal protons is visible in both spectra (marked with an arrow). In contrast, no TOCSY transfer is observed between the geminal protons at 2.6 and 2.7 ppm, although they are even more strongly coupled than the protons mentioned above. This is probably due to the oscillatory behavior of TOCSY transfer, which vanishes for the chosen mixing time for the pair of geminal protons at 2.6 and 2.7 ppm. The example shows that a careful analysis of ROESY spectra is mandatory for signals close to the diagonal

exploited to suppress cross relaxation in exchange spectra of macromolecules.³² For large ($\omega\tau_c \gg 1$) or intermediate sized ($\omega\tau_c \approx 1$) molecules, the unmodified mixing scheme $(\pi_x\pi_{-x})_n$ yields a net ROE rate of only $\frac{1}{4}\sigma_{\text{ROE}}$ or $\frac{1}{2}\sigma_{\text{ROE}}$ on resonance,³⁰ since $w_1 = w_t = \frac{1}{2}$. It is therefore of interest to increase the weight of transverse cross relaxation. This can be achieved using shaped pulses (Figure 8b), or by the introduction of delays into the sequence (Figure 8c).

In the following, ROESY sequences will be compared that yield equal net cross-relaxation rates on-resonance and that dissipate the same power in a sample. Figure 9 shows the offset behavior of cross relaxation of JS ROESY [(a): $\theta = 53.77^\circ$] and of a phase-alternating ROESY employing a shaped 180° pulse to increase w_t . (b):³¹

The offset dependence of the cross relaxation of the JS ROESY sequence is somewhat less pronounced than that of the phase-alternating sequence.

In Figure 9(c), the scaling λ is plotted as a function of the offset for both sequences. The minimal λ of the two spin locks is plotted for JS ROESY, since λ may not be averaged in the case of extended stretches of CW irradiation. On-resonance, λ is larger for JS ROESY than for the phase-alternating sequence. This result is a direct consequence of the fact that the scaling of λ in CW sequences is minimal at given w_t . For larger offsets, the phase-alternating sequence yields a somewhat better suppression of TOCSY (larger λ). Although λ can serve as a measure of TOCSY transfer along the diagonal only, this reasoning shows that it appears to be worthwhile to search for optimized ROESY sequences that minimize the loss in λ on-resonance while achieving maximum λ off-resonance.

Figure 10 shows a comparison of JS ROESY and the phase-alternating ROESY sequence. The spectra differ only marginally. Coherent transfer is well suppressed, except for the two strongly coupled geminal protons H-6', H-6''. For more details, see the figure legend.

1 INTRODUCTION

Two-dimensional correlation spectroscopy, originally proposed by Jeener¹ in 1971, was developed by Ernst et al.² and abbreviated with the term COSY. Since then, this method has played the most important role in the structure elucidation of organic compounds. In 1978, Freeman and Morris³ created the polarization transfer experiment to correlate chemical shifts of carbons and protons. This type of H,C COSY experiment dominated the following decade because it could be easily implemented on FT spectrometers which were constructed for proton-decoupled carbon NMR measurements. Although the more attractive ‘inverse’ (i.e. proton) detection was invented in the early 1980s,⁴ these new methods struggled because the existing spectrometer generation did not support the necessary phase coherence between the proton decoupler and the receiver. Since 1989, inverse detection has been a standard feature of modern commercial instruments. For the inverse H,C COSY experiment, two pulse sequences were used: HMQC⁵ and HSQC.⁶ The main difference between them is the order of the coherence which is relevant to the information transfer between the nuclei. The abbreviations HMQC and HSQC refer to Heteronuclear *Multiple* and *Single* Quantum Coherence, respectively.

Heteronuclear correlation spectroscopy is not restricted to the spin pair ¹H,¹³C. ¹H,ⁿX correlations are also used for structure elucidation, e.g. ¹H,³¹P for organophosphorus compounds. In fact, the inverse experiments were introduced for the spin pair ¹H,¹⁵N. Today, indirect detection is the method of choice for rare nuclei.

The molecular skeleton, however, is usually made from carbon. In organometallic, bioorganic, and heterocyclic chemistry we find, in addition, one or more heteroelements embedded in the carbon framework, whereas the protons only cover the outer surface of the molecule. It is therefore straightforward to create 2D NMR methods to detect directly the connectivity between the carbon atoms and magnetically active heteroelements. In this article we review the hardware requirements needed for this purpose, discuss a variety of pulse methods

used, and discuss the chemical applications achieved so far with these techniques.

2 SELECTION OF NUCLEI

Possible correlation partners of ¹³C are all spin $\frac{1}{2}$ nuclei, such as ¹⁹F, ¹⁵N, ³¹P, ²⁹Si, ⁷⁷Se, ¹¹⁹Sn, ¹²⁵Te, ¹⁹⁵Pt, ¹⁹⁹Hg, or ²⁰⁷Pb. For special applications quadrupolar nuclei such as ²H, ⁶Li, or ¹¹B may also be of interest. Of course, the relative importance of these correlations is dictated by the chemistry of these classes of compounds. In a ¹³C,ⁿX correlation one is faced with the question of which nucleus one should detect and which should develop chemical shift during *t*₁. There are complex arguments based on the pulse sequences used, the *T*₁ and *T*₂ relaxation times of the two nuclear species involved, the spectral width required in both the *F*₁ and *F*₂ dimensions, and many more. At first sight, perhaps surprisingly, the natural abundance of a nucleus gives no direct argument, since for correlation NMR it is always the product of both natural abundances that is decisive. There is, however, a practical reason why the relative natural abundances have to be considered. In the case of, for example, a ¹³C,³¹P correlation, each rare ¹³C spin ‘sees’ a phosphorus, whereas only 1% of the phosphorus atoms ‘see’ a ¹³C spin. The suppression of unwanted signals must therefore be rather efficient if one is to detect the nucleus with the higher abundance.

Next, one should consider the linewidth of the 1D spectra of both nuclei. The detected nucleus should be the one with the smaller linewidth, since a short *T*₂ leads to signal losses during the pulse sequence. In the case of ¹³C,ⁿX correlations (ⁿX = ⁷⁷Se, ¹²⁵Te, ¹⁹⁵Pt, ¹⁹⁹Hg, and ²⁰⁷Pb), carbon has the smaller linewidth. Because of the chemical shift anisotropy and the temperature dependence of the chemical shift of heavy nuclei, the measurement of ¹³C would therefore be favored in these cases.

For carbon detection, in addition, the large NOE enhancement caused by proton irradiation has to be taken into account. Heteronuclei usually have no directly bound proton, their NOE factors are therefore usually less than the maximum value. To facilitate further discussion, the γ values and the natural abundances of the nuclei used for ¹³C,ⁿX correlation are given in Table 1.

Table 1 Gyromagnetic Ratios and Natural Abundances of Selected Nuclei

Nucleus	γ (10 ⁷ rad T ^{−1} s ^{−1})	Natural abundance
² H	4.106	0.015
⁶ Li	3.937	7.42
¹¹ B	8.583	80.42
¹³ C	6.726	1.108
¹⁵ N	−2.711	0.37
¹⁹ F	25.166	100
²⁹ Si	−5.314	4.7
³¹ P	10.829	100
⁷⁷ Se	5.101	7.58
¹¹⁹ Sn	−9.971	8.58
¹²⁵ Te	−8.452	6.99
¹⁹⁵ Pt	5.75	33.8
¹⁹⁹ Hg	4.769	16.84
²⁰⁷ Pb	5.597	22.6

By inspection of Table 1, it is possible to group the possible correlation partners of carbon into three classes. One group has lower γ values (^2H , ^6Li , ^{15}N), one group quite comparable γ values (^{29}Si , ^{195}Pt , ^{199}Hg , ^{207}Pb), and a third group definitively higher γ values (^{11}B , ^{19}F , ^{31}P , ^{119}Sn , ^{125}Te). For this last group, therefore, using the HMQC method, ^nX detection should be preferable if arguments based on γ values were the only factors. However, even in this group polarization transfer with carbon detection might be competitive, since the higher γ value of the X nucleus is transferred to the carbon signal, and this itself is enhanced by NOE.

The repetition time of these experiments is governed by the T_1 relaxation of nucleus 1 in HMQC and HSQC, but of nucleus 2 in the polarization transfer experiment. At high magnetic fields, heteronuclei relax not only by dipolar but also, to a considerable extent, by other relaxation mechanisms such as chemical shift anisotropy. Hence, the relaxation times of metal nuclei are very often in the range of 1 s. This again would favor the HMQC method with ^nX detection or the polarization transfer method with ^{13}C detection.

A final argument stems from the required spectral width in both dimensions. It is very inconvenient to have a large spectral width in F_1 because this would be very time-consuming; furthermore, signal folding in F_1 cannot be filtered out. Thus, it is often better to detect the nucleus with the larger spectral width. In addition, this can be more easily separated into different parts if the spectral width is too large to allow reasonably uniform 180° pulses.

3 HARDWARE CONSIDERATIONS

The experiments described in this article are usually performed under complete proton decoupling. Thus, in addition to the ^1H coil and the standard ^2H lock signal, one needs two more frequencies to be delivered to the sample. The simplest approach would be a fixed probehead, with an additional coil double-tuned to, for example, ^{13}C and ^{15}N . This is very popular in protein research, because proteins doubly labeled with ^{13}C and ^{15}N are now fairly readily available. The drawback of such a probehead is obvious; it is restricted to the special spin triple ^1H , ^{13}C , ^{15}N , and no other experiment is possible. A second approach would be to have one multinuclear tuneable coil, and double tune the second X nucleus to the ^1H coil. One has to decide which X nucleus to choose. For the experiments described here, ^{13}C was chosen since in organoelement chemistry carbon is the common denominator. The spectrometer needs an independent third radiofrequency channel, which can deliver its pulses to the appropriate coil of the probehead. Such a third radiofrequency channel usually requires a second frequency synthesizer, some gating electronics, and a power amplifier. The feature of a third radiofrequency channel is standard in research instruments built later than 1990; however, it has been adapted in many NMR laboratories to older instruments.

4 SELECTION OF PULSE METHODS

The basic pulse sequences known from ^{13}C , ^1H correlation have all been adapted for ^{13}X , ^nX correlation under proton

decoupling. In Figure 1 the three common pulse sequences are shown.

In the HMQC technique [Figure 1(a)], transverse magnetization of nucleus 1 is first generated. Antiphase magnetization which evolves during the first delay is transferred to nucleus 2 which evolves under the chemical shift during t_1 . This is transferred back to nucleus 1. During the final acquisition time, t_2 , the chemical shift of nucleus 1 and heteronuclear coupling to nucleus 2 evolve; thus, at the end of this pulse sequence we measure the magnetization which originates from the equilibrium magnetization of the detected nucleus. Neglecting, at this stage, relaxation arguments, the overall sensitivity⁷ of the HMQC sequence is then proportional to $\gamma_1^{5/2}$. Thus, for a ^{13}C , ^nX correlation with this technique, theory strongly suggests the choice of the nucleus with the higher γ value as the detected nucleus.

The HSQC sequence [Figure 1(b)] consists of two INEPT sandwiches, which are separated by the evolution time t_1 . Here we again start with the equilibrium magnetization of nucleus 1. If we compare the magnetization transfer ways with the HMQC method, we realize that in both experiments the same equilibrium magnetization is finally used for detection; hence, the sensitivity arguments stay the same. For the application discussed here, homonuclear spin couplings can be neglected and thus the HSQC method should yield comparable results to HMQC. The HMQC experiment, however, does need more than double the number of radiofrequency pulses. For practical reasons of error propagation, it might therefore be less favorable. Another point of discussion would be the different relaxation properties of single- and multiple-quantum coherences which, in the case of heteronuclear correlation, are not predominant.

In contrast to the HMQC and the HSQC experiment, transverse magnetization of nucleus 2, which is **not** detected later, will be created in the beginning of the polarization transfer experiment [Figure 1(c)]. In the following evolution time this magnetization is modulated with the chemical shift of nucleus 2. Since nucleus 1 is detected, the overall sensitivity in this experiment⁷ is related to the factors $\gamma_1^{3/2}\gamma_2$; hence, the choice of the detected nucleus is not as obvious as in the two former pulse sequences. There is a further point to be considered in a comparison of the three pulse sequences. In both HMQC and HSQC magnetization is transferred twice, forwards and backwards, between the two nuclei. In the polarization transfer method this occurs only once. If this transfer is not optimal due to a range of different spin coupling constants, there are inevitable losses of signal in each transfer; thus, the method with only one transfer might be favored. Modifications of the above pulse sequences employ an INEPT transfer from protons to one heteronucleus prior to the start of the actual correlation.^{8,9}

5 CHEMICAL APPLICATIONS

5.1 ^{13}C , ^{31}P Correlation

Most of the published work has been performed on the spin pair ^{13}C , ^{31}P ; hence, it seems appropriate to review this nucleus first. Martin and co-workers¹⁰ showed the feasibility of this technique with a homebuilt probe and the HMQC

method. They used triphenylphosphane oxide as an example. Since the spectrometer used did not have three rf channels, proton decoupling could not be employed. Of course, 2D correlation on this simple compound does not give new chemical insights, it merely served as a model compound. A more systematic study compared the three pulse methods taking triphenylphosphane as an example using ^{31}P and ^{13}C detection.¹¹ The merits of the different methods were discussed and it was found that for ^{31}P detection the polarization

transfer method was the most suitable; for ^{13}C detection the HMQC method was the most suitable. As a first real example, the ^{13}C , ^{31}P correlation of nicotinamide adenine dinucleotide (NAD^+) was measured. This example is given in Figure 2 and shows very nicely the ease of assignment with such methods. Further examples given by Bast et al.¹¹ were a mixture of mononucleotides.

Examples from the chemistry of phosphonates have been published by Grossmann and co-workers.¹² For a mixture of stereoisomeric diphosphonates they could, with the help of ^{13}C , ^{31}P correlation, assign the three different sets of signals and determine the P, P' spin coupling constant in these compounds. Other examples from the same group include bis(dialkoxythiophosphoryl) sulfides and their polysulfides.¹³ An example from the field of ligands used in organometallic chemistry is provided by the molecule prophos (see Figure 3) in which we find all the phenyl groups to be inequivalent due to chirality, and one might question the relative assignments of these carbon atoms.¹⁴ The ^{31}P NMR spectrum is easily assigned via H,P correlation. Phosphorus A ($\delta = -25$ ppm) couples with all aliphatic protons while phosphorus B ($\delta = -4.7$ ppm) only couples with the methylene and methine group. The phosphorus-substituted *ipso*-carbon atoms of the four phenyl rings are particularly difficult to assign by any other method. In Figure 3 the extension of a 2D ^{13}C , ^{31}P correlation is shown, which immediately relates the connectivity of the pairs of diastereotopic *ipso*-carbon atoms with their corresponding phosphorus atoms. Close inspection of Figure 3 reveals, from the slant of the cross peaks, that the signs of the $^1J(\text{P}, \text{C})$ and $^3J(\text{P}, \text{P})$ spin coupling constants are the same; $^1J(\text{P}, \text{C})$ spin coupling constants for threefold coordinated phosphorus are known to be negative.¹⁵ The possibility of evaluating the relative sign of coupling constants can be viewed as a further asset of ^{13}C , X correlations.

Very recently, ^{19}F , ^{13}C correlations have been published.^{27–29}

5.2 ^{13}C , ^{15}N Correlation

The ^{13}C , ^{15}N correlation is especially important in the protein field and was therefore, up to now, only applied in this class of compounds. Doubly-labeled material has to be used, but this is readily available by biological methods. Using the HMQC method, the first paper in this field¹⁶ correlated the signals of

Figure 1 Pulse sequences for X,Y correlation under proton decoupling. (a) HMQC pulse sequence adapted for X,Y correlation; P1, P2, and P4 represent 90° pulses, P3 a 180° pulse, $D1$ = relaxation delay, $\Delta = \frac{1}{2}J(\text{X}, \text{Y})$. The pulse and receiver phases are: P1, P3: x, P2: x, $-x$, incremented by time proportional phase incrementation (TPPI), P4: x, x, $-x$, $-x$, rec: x, $-x$, $-x$, x. (b) HSQC pulse sequence adapted for X,Y correlation under ^1H decoupling; P1, P4, P5, P7, and P8 represent 90° pulses, P2, P3, P6, P9, and P10 180° pulses, $D1$ = relaxation delay, $\Delta = \frac{1}{4}J(\text{X}, \text{Y})$. The pulse and receiver phases are: P1, P2, P6, P9: x, P3, P10: $(x)_4$, $(-x)_4$, P4, P7: y, P5: x, $-x$, incremented by TPPI, P8: x, x, $-x$, $-x$, rec: x, $-x$, $-x$, x. (c) Polarization transfer sequence adapted for X,Y correlation under ^1H decoupling; P1, P5, and P6 represent 90° pulses, P2, P3, P4, P7, and P8 180° pulses, $D1$ = relaxation delay, $\Delta = \frac{1}{4}J(\text{X}, \text{Y})$. The pulse and receiver phases are: P1: x, P2, P3, P4, P7: x, x, $-x$, $-x$, P5: y, $-y$, incremented by TPPI, P6: $(x)_4$, $(y)_4$, $(-x)_4$, $(-y)_4$, P8: $(x)_2$, $(-x)_2$, $(y)_2$, $(-y)_2$, rec: $(x, -x)_2$, $(y, -y)_2$, $(-x, x)_2$, $(-y, y)_2$.

a protein of molecular weight of 20 000 Da (see Figure 4). A huge number of cross peaks describing the amide links of the protein can be seen. After methodical research on labeled acetamide⁸ to find the best possible pulse sequence, another group used this method to elucidate the structure of a cyclic decapeptide.¹⁷

5.3 Correlation with Metal Nuclei

This application of correlation spectroscopy is very recent. For ^{29}Si , a new pulse sequence, a combination of INEPT and HMQC, was proposed and applied to decamethyltetrasiloxane as a model compound and to a polymer silicon oil as an example.⁹ This technique has also been used in organoselenium chemistry, where, for example, a full assignment of the ^{13}C and ^{77}Se chemical shifts could be achieved for olefins bearing two different phenylseleno groups. Furthermore, incorrect literature structures could be corrected.¹⁸ Another olefin

Figure 4 2D ^{13}C , ^{15}N correlation of ^{13}C and ^{15}N labeled flavodoxin from *Anabaena* 7120 (taken from Westler et al.¹⁶)

with two different trimethyltin groups served as the first example for ^{13}C , ^{119}Sn correlation.¹⁹ It was shown that long range coupling constants can also be used to correlate carbon and tin chemical shifts. Conformational assignment can therefore be made by these means. Recently, two examples from organomercury²⁰ and organolead²¹ chemistry have been tested.

5.4 Correlation with Quadrupolar Nuclei

Although, at first sight, 2D correlation spectroscopy of ^{13}C with quadrupolar nuclei does not seem feasible due to relaxation problems, there are two nuclei where, due to the relatively small quadrupolar moment, such a correlation has been performed, i.e. the ^2H and the ^6Li nuclei. Günther and co-workers were the first to employ these methods for both nuclei. For ^2H they chose 2,4,5,6-pyridine- d_4 as an example

Figure 5 2D $^{13}\text{C}, ^{11}\text{B}$ correlation of 1,7-dicarba-closo-dodecaborane(12) (taken from Fäcke and Berger²⁶)

to test the correlation technique²² and, later on, applied this to the analysis of isotopomeric mixtures of bicyclic compounds in which the deuterium label was distributed during a chemical reaction.²³ By means of the $^{13}\text{C}, ^2\text{H}$ correlation the signals in this mixture could be easily assigned. For this technique, the usual ^2H lock of modern instruments cannot be used and must be replaced by a ^{19}F lock system. In organolithium compounds one is often faced with dynamic equilibria between aggregates of different sizes, depending on temperature and solvent. The structures obtained by X-ray crystallography do not necessarily correspond to those predominant in solution. In two reports^{24,25} it was shown that a 2D $^{13}\text{C}, ^6\text{Li}$ correlation can contribute to the analysis of organolithium compounds. Carboranes and metallacarboranes provide a large class of compounds where sometimes, due to symmetry reasons, the ^{11}B signals display reasonably small linewidths on the order of the $^{13}\text{C}, ^{11}\text{B}$ spin coupling constant. A $^{13}\text{C}, ^{11}\text{B}$ correlation was therefore attempted for selected carboranes. In Figure 5 the result for the *meta*-dodecaborane (**1**) is shown,²⁶ displaying nicely the different connections within this cage compound.

6 CONCLUSIONS

We have shown in this article the feasibility and possibilities of 2D $^{13}\text{C}, ^n\text{X}$ correlation, and demonstrated that this technique often provides a very direct and straightforward signal assignment. The further development and application of these techniques will certainly give new possibilities in structural elucidation in the field of organoelement chemistry.

1 INTRODUCTION

J-resolved 2D spectroscopy (also commonly known as 2D *J* spectroscopy) is a class of two-dimensional NMR methods that separate chemical shifts from multiplet structure. In pulse sequences for *J*-resolved 2D spectroscopy, a 180° pulse is applied at the centre of the evolution period t_1 , generating a spin echo. The modulation of spin echoes by scalar coupling causes signals to be dispersed in the f_1 domain of the resultant 2D spectrum according to their position within scalar coupling multiplets. This allows the separation of multiplet structure from chemical shifts, improving the resolution of individual signals in spectra with overlapping multiplets. There is a further gain in resolution in the f_1 domain of the 2D spectrum, because the spin echo suppresses the effects of B_0 inhomogeneity, giving f_1 linewidths approaching the natural limit $1/\pi T_2$. *J*-resolved 2D spectroscopy is now much less widely used than correlated 2D methods, but still finds application, for example in the analysis of complex spin systems and in the separation of homonuclear from heteronuclear coupling structure.

Both homonuclear and heteronuclear multiplet structure can be investigated by *J*-resolved spectroscopy. Since broadband suppression of homonuclear couplings during measurement of the free induction decay is not possible, homonuclear *J*-resolved 2D spectroscopy¹ produces spectra with multiplet structure in f_1 , and both multiplet structure and chemical shifts in f_2 . In heteronuclear *J*-resolved 2D spectroscopy,^{2,3} on the other hand, it is normal to apply broadband decoupling during data acquisition, so that multiplet structure is suppressed in f_2 and a complete separation is achieved between multiplet structure in f_1 and chemical shifts in f_2 . For weakly coupled spin systems, a similar separation can be achieved in homonuclear *J*-resolved 2D spectroscopy by ‘shearing’ or ‘tilting’ the 2D data matrix¹ to give a 45° tilt in frequency space:

$$S(f_1, f_2) = S(f_1, f_2 - f_1) \quad (1)$$

A further difference between homonuclear and heteronuclear methods lies in the origin of the echo modulation. In the homonuclear experiment, the modulation arises naturally from the action of the 180° pulse used to generate the spin echo, since it affects both the partners in any scalar coupling. In the

heteronuclear experiment, couplings to weakly coupled heteronuclei do not give rise to any modulation of the spin echo unless a suitable perturbation is applied to the heteronuclei.

The simplest form of *J*-resolved spectroscopy is the homonuclear experiment of the following sequence, in which the basic Carr–Purcell method A spin echo sequence⁴ forms the evolution period of a 2D experiment:

$$90^\circ \quad \frac{1}{2}t_1 \quad 180^\circ \quad \frac{1}{2}t_1 \quad \text{Acquire} \quad (2)$$

This experiment is normally used in proton NMR, but is applicable to any nuclei with homonuclear couplings. Because the resulting signals are phase-modulated with respect to t_1 , it is not normally practicable to use phase-sensitive display. In order to secure acceptable absolute value mode lineshapes, it is usual to apply either pseudoecho⁵ or sine-bell⁶ weighting in both frequency dimensions, despite the signal-to-noise ratio penalty. This forces the time domain signals into an approximately symmetric envelope, so that dispersion-mode contributions (which have odd symmetry) are absent from the resultant frequency domain lineshapes.

Sequence (2) will not normally generate any echo modulation as a result of heteronuclear couplings; this is the basis of the use of homonuclear *J*-resolved spectroscopy to distinguish between homonuclear and heteronuclear multiplet structure. (Echo modulation due to heteronuclear couplings can arise, however, if there is coupling to a group of heteronuclei that are strongly coupled amongst themselves.⁷) For simplicity, it will be assumed here that the nucleus being observed is ¹³C and that the coupled nuclei are protons. Although the great majority of experimental applications of heteronuclear *J*-resolved spectroscopy are to this pair of nuclei, there are of course many other possibilities.

Two methods are commonly used to ensure that heteronuclear couplings generate echo modulation. In the ‘gated decoupler’ method,^{2,3,8,9} broadband decoupling is applied during one half only of the evolution period t_1 ; decoupling is normally also used during the preparation period (to provide the NOE) and during measurement of the free induction decay (to remove multiplet structure from f_2):

$$\begin{array}{ccccccc} {}^1\text{H} & \leftarrow & \text{Decouple} & & \rightarrow & & \leftarrow \text{Decouple} \rightarrow \\ {}^{13}\text{C} & & 90^\circ & \frac{1}{2}t_1 & 180^\circ & \frac{1}{2}t_1 & \text{Acquire} \end{array} \quad (3)$$

This gives a 2D spectrum in which the multiplet structure is scaled down to half its normal width in f_1 , but otherwise faithfully reflects the conventional spectrum, even where there is strong proton–proton coupling.

The second, ‘proton flip’, technique^{3,8,10} uses a 180° pulse to invert the coupled heteronuclei at the midpoint of the evolution period; again, decoupling is normally used during the preparation and detection periods:

$$\begin{array}{ccccccc} {}^1\text{H} & \leftarrow & \text{Decouple} & & \rightarrow & & \leftarrow \text{Decouple} \rightarrow \\ {}^{13}\text{C} & & 90^\circ & \frac{1}{2}t_1 & 180^\circ & \frac{1}{2}t_1 & \text{Acquire} \end{array} \quad (4)$$

Here the multiplet structure appears without any scaling, but only matches that in the 1D spectrum if the heteronuclei (here protons) are weakly coupled. The analysis of strongly coupled proton flip *J*-resolved spectra is discussed in Section 3.2, and closely parallels the analysis for the homonuclear case.

2 HISTORICAL REVIEW

The earliest use of Fourier transformation of the dependence of echo amplitude on the spin echo delay t_1 was the

'*J* spectroscopy' experiment of Freeman and Hill.¹¹ This involved measuring the amplitude of the signal at the peak of the echo for a series of equally spaced values of t_1 , and Fourier transformation with respect to t_1 to generate a '*J* spectrum' in which chemical shifts and line broadening due to field inhomogeneity were suppressed. This experiment was of little practical utility, because all the multiplets in a spectrum were superimposed, so that only the simplest of spin systems could be studied. The effect of measuring just the single data point at the maximum of the echo is equivalent to carrying out an integral projection of a 2D *J*-resolved spectrum onto the f_1 axis.

The first two-dimensional experiments to use spin echoes were reported in Aue, Bartholdi, and Ernst's classic introductory paper¹² on 2D NMR; these were effectively COSY experiments with 180° mixing pulses. Homonuclear *J*-resolved spectroscopy proper was introduced a few months later,¹ in a communication that pointed out the possibility of obtaining a 'decoupled' proton spectrum from a 45° projection. The first heteronuclear experiments were proposed independently by Freeman and co-workers shortly afterwards.² Heteronuclear *J*-resolved spectroscopy proved a useful vehicle for the technical development of 2D NMR,¹³ since it required only modest data storage.

The observation of artifacts caused by imperfect 180° pulses prompted the development of EXORCYCLE,¹⁴ one of the first and most widely used phase cycling techniques; the acronym derived from the use of the terms 'ghost' and 'phantom' for the spurious signals. The differences in multiplet structure between gated decoupler and proton flip heteronuclear *J*-resolved spectra seen in the presence of strong proton–proton coupling^{8–10} led to the development of analytical solutions and numerical software for calculating strongly coupled homonuclear and proton flip heteronuclear *J*-resolved spectra.^{10,15,16} Heteronuclear *J*-resolved spectroscopy was also the vehicle for early investigations of the problem of lineshapes in phase-sensitive 2D spectra. Phase modulation leads to 'phasetwist' lineshapes, which are an inseparable mixture of 2D absorption and dispersion mode lineshapes.¹³ This problem can be cured in heteronuclear *J*-resolved spectra by combining results from two experiments that have opposite senses of precession in t_1 ; the apparent sense of precession can be reversed either by adding a second 180° pulse at the end of the evolution period¹⁷ or, in the gated decoupler experiment, by changing from decoupling during one half of t_1 to decoupling in the other.¹⁸ Such expedients are actually seldom used, since in f_2 -decoupled heteronuclear *J*-resolved spectroscopy, phase-sensitive f_1 cross-sections (which can be phased to absorption mode, since they pass through the midpoints of the phasetwisted lineshapes) can usually be obtained free of overlap from neighboring signals in f_2 .

With the introduction of better spectrometer computers, *J*-resolved spectroscopy was quickly eclipsed by the more powerful and general class of correlated 2D experiments such as COSY and NOESY, but, nevertheless, a number of useful extensions have been demonstrated. Making the 180° proton pulse of sequence (4) selective restricts the modulation of the spin echo to couplings to protons with a particular chemical shift.¹⁹ If the carbon and proton 180° pulses of a proton flip experiment are replaced by a BIRD (bilinear rotation decoupling) sequence,²⁰ the refocusing can be made selective for either long-range or one-bond heteronuclear couplings.

This is known as semiselective *J* spectroscopy,²¹ giving *J*-resolved spectra in which, depending on the relative phases of the pulses in the BIRD sequence, either the one-bond or the longer range couplings are removed from the f_1 dimension, simplifying analysis. Again, strong proton–proton coupling can complicate spectra very considerably, but numerical simulations can be performed;²² the large number of lines produced can actually be an advantage, because it increases the accuracy with which spin system parameters may be derived.

Another extension is known as indirect *J* spectroscopy;^{23,24} this adds a polarization transfer step to a proton spin echo, transferring the proton *J* modulation to ¹³C signals. This works well where the ¹³C satellites in the proton spectrum are weakly coupled, allowing clean resolution of individual proton multiplets, even in systems where the proton spectrum is completely unresolved. It has been little used, however, and for most purposes a high- f_2 -resolution HMQC experiment²⁵ is preferable; this does not give any proton linewidth improvement, but is quicker, and doubles the chances of avoiding strong coupling if run without ¹³C decoupling in t_2 .

3 THEORY

3.1 Weak Coupling

Consider first a weakly coupled homonuclear system of two spins $\frac{1}{2}$, *I* and *S*; the energy level diagram and spectrum are shown in Figure 1. There are two *I* transitions: one for the half of the spin systems in which *S* is in the α state and one for those in which it is β , and a similar pair of *S* transitions. Initially, the magnetizations for the four transitions will be at equilibrium; the state of the spin system may be represented in the product operator formalism²⁶ as $\hat{I}_z + \hat{S}_z$, and the four magnetizations will point along the *z* direction in the rotating frame of reference. The initial 90° pulse of sequence (2) will rotate the four magnetizations down to the $-y$ axis of the rotating frame to give $-\hat{I}_y - \hat{S}_y$; the *I*-spin magnetizations are shown diagrammatically in Figure 2(a). During the first half of the evolution period, the chemical shifts of spins *I* and *S* will cause the magnetizations to precess through angles $\phi_I = \pi\delta_I t_1$ and $\phi_S = \pi\delta_S t_1$ (in rad), respectively, where δ_I and δ_S are the offsets from resonance (in Hz) of the two spins. The scalar coupling J_{IS} will cause the two components of each multiplet to diverge by an angle $\theta_1 = \pi J_{IS} t_1$, giving the state

$$\begin{aligned} -\hat{I}_y \cos = & \phi_I \cos \frac{1}{2}\theta_1 + \hat{I}_x \sin \phi_I \cos \frac{1}{2}\theta_1 + 2\hat{I}_x \hat{S}_z \cos \phi_I \sin \frac{1}{2}\theta_1 \\ & + 2\hat{I}_y \hat{S}_z \sin \phi_I \sin \frac{1}{2}\theta_1 - \hat{S}_y \cos \phi_S \cos \frac{1}{2}\theta_1 + \hat{S}_x \sin \phi_S \cos \frac{1}{2}\theta_1 \\ & + 2\hat{S}_x \hat{I}_z \cos \phi_S \sin \frac{1}{2}\theta_1 + 2\hat{S}_y \hat{I}_z \sin \phi_S \sin \frac{1}{2}\theta_1 \end{aligned} \quad (5)$$

for which the *I* magnetizations are shown in Figure 2(b); for the time being, relaxation will be neglected. The 180° pulse,

Figure 1 Energy level diagram and spectrum for a weakly coupled *IS* system of two spins $\frac{1}{2}$

Figure 2 Motion of the two I magnetizations in a weakly coupled IS system of two spins $\frac{1}{2}$ during sequence (2)

applied about the x axis in the rotating frame, will have two effects. It will change the signs of all the terms in $\hat{I}_y$ and $\hat{S}_y$, reflecting the corresponding magnetization vectors about the (x, z) plane of the rotating frame. It will also invert all terms in $\hat{I}_z$ and $\hat{S}_z$; this corresponds to interchanging α and β spins, so that, for example, the I magnetization associated with transition 12 before the 180° pulse (for which S is in the α state) is transferred to transition 34 ($S = \beta$), giving the situation shown in Figure 2(c).

During the second half of the evolution period, the I and S magnetizations will again precess through angles ϕ_I and ϕ_S respectively, and the two components of the I and S pairs will again diverge by $\frac{1}{2}\theta_1$ radians. The effect of the chemical shift precession during the second half of t_1 exactly matches the shift precession during the first half, so that in the absence of any coupling J_{IS} , all four magnetizations would refocus along the $\hat{I}_y$ axis. In the presence of a coupling, the two components of the I and S multiplets end up disposed symmetrically either side of the $\hat{I}_y$ axis, an angle θ apart (Figure 2d), giving the state $+\hat{I}_y \cos \theta_1 - 2\hat{I}_x \hat{S}_z \sin \theta_1 + \hat{S}_y \cos \theta_1 - 2\hat{S}_x \hat{I}_z \sin \theta_1$. The signal at time t_1 is thus unaffected by chemical shifts (or inhomogeneity of the static magnetic field): a spin echo is produced, which is modulated only by the scalar coupling J_{IS} . Each multiplet is a mixture of in-phase absorption mode signals ($\hat{I}_y$) and antiphase dispersion signals ($2\hat{I}_x \hat{S}_z$); the net effect of the modulated spin echo is to multiply one multiplet component by a phase factor $e^{-i\pi J_{IS} t_1}$ and the other by $e^{i\pi J_{IS} t_1}$.

At time t_1 , the second half of the modulated echo is recorded as a free induction decay $S(t_2)$. Neglecting relaxation, the complex signal $S(t_1, t_2) = M_y - iM_x$ recorded can then be written as

$$S(t_1, t_2) = \frac{1}{2} (e^{i\pi J_{IS} t_1} e^{i(2\pi \delta_I + \pi J_{IS}) t_2} + e^{-i\pi J_{IS} t_1} e^{i(2\pi \delta_I - \pi J_{IS}) t_2} + e^{i\pi J_{IS} t_1} e^{i(2\pi \delta_S + \pi J_{IS}) t_2} + e^{-i\pi J_{IS} t_1} e^{i(2\pi \delta_S - \pi J_{IS}) t_2}) \quad (6)$$

which consists of four signals with frequency coordinates (f_1, f_2) of $(\frac{1}{2}J_{IS}, \delta_I + \frac{1}{2}J_{IS})$, $(-\frac{1}{2}J_{IS}, \delta_I - \frac{1}{2}J_{IS})$, $(\frac{1}{2}J_{IS}, \delta_S + \frac{1}{2}J_{IS})$ and $(-\frac{1}{2}J_{IS}, \delta_S - \frac{1}{2}J_{IS})$: the signals are dispersed according to their normal frequencies $\delta \pm \frac{1}{2}J_{IS}$ in f_2 , and with just their multiplet structure $\pm \frac{1}{2}J_{IS}$ in f_1 . The extension to larger spin systems is straightforward.

The same logic can be applied to heteronuclear J -resolved experiments. The analysis of the proton flip method parallels that for the homonuclear case, except that the initial 90° pulse affects only (say) spin I , so that all terms in $\hat{S}_x$ and $\hat{S}_y$ disappear. In the gated decoupler method, the use of broadband S -spin decoupling during the first half of the evolution period suppresses the effects of J_{IS} in the first half of t_1 , so that the frequencies in f_1 are halved to $\pm \frac{1}{4}J_{IS}$. In both methods, broadband decoupling is normally used during t_2 to remove multiplet structure from f_2 .

3.2 Strong Coupling

In the presence of strong coupling, the simple analysis given in Section 3.1 breaks down, and it is generally necessary to use density matrix theory. Although analytical results have been presented for some simple spin systems,¹⁶ it is usual to employ numerical methods; a modified version of the 1D spin simulation program LAOCN3,²⁷ SONOFLAOCOON,¹⁰ may be used both for simulation and for iterative analysis of strongly coupled J -resolved spectra.

Consider a system containing two weakly coupled groups of spins I and S , either of which may be strongly coupled, where only the spins I are to be observed. In the heteronuclear case [sequence (4)], group I will generally contain a single ^{13}C spin and S the coupled protons; in the homonuclear case [sequence (2)], all the spins will belong to group I . If the matrix representation of the q component of spin angular momentum for group I is denoted by $\mathbf{I}^q$, the initial reduced density matrix ρ_0^I for group I will be equal to some constant m_0 times $\mathbf{I}^z$, and the effect of the 90° I pulse will be to rotate ρ_0 into $-m_0 \mathbf{I}^y$. If calculations are performed in the eigenbasis, the ij th element of ρ^I at time $\frac{1}{2}t_1$ will be $-m_0 \exp[i\pi t_1(v_i - v_j)] I_{ij}^y$, where v_i is the i th energy eigenvalue of the spin system (in Hz). If the matrix representation for 180° rotation of spins I and S is $\mathbf{T}^{IS}$ then the effect of the 180° I and S pulses will be to transfer coherences ρ_{ij} into other coherences ρ_{kl} :

$$\rho_{kl} = \sum_i \sum_j \rho_{ij} T_{ik}^{IS*} T_{jl}^{IS} \quad (7)$$

Thus, at the end of the evolution period, the total y signal will be

$$S = -m_0 \sum_i \sum_j \sum_k \sum_l I_{ij}^y T_{ik}^{IS*} T_{jl}^{IS} I_{lk}^y \times \exp[i\pi t_1(v_i - v_j + v_l - v_k)] \quad (8)$$

The 2D J -resolved spectrum thus consists of a series of responses S_{ijkl} of f_1 frequencies $\frac{1}{2}(v_i - v_j + v_l - v_k)$, with intensities given by the preexponential terms in equation (8). Only when all spins are weakly coupled are the f_1 frequencies determined solely by coupling constants; where there is strong coupling, they will also contain terms in chemical shifts (often leading to folding in f_1), and the signals may have negative intensity.

The calculation of a 2D J -resolved spectrum thus reduces to the diagonalization of the nuclear spin Hamiltonian, as in conventional spin simulation programs such as LAOCN3,²⁷ followed by construction of the eigenbasis matrix representations of the y component of angular momentum and of the 180° rotation operator. By suitable choice of the groups of spins I and S , the same program may be used to calculate

4 TWO-DIMENSIONAL *J*-RESOLVED SPECTROSCOPY

Table 1 Phase Cycling for Sequences (2)–(4); Phase Shifts are Indicated as Multiples of 90° for the 90° Pulse (ϕ_1), 180° Pulse (ϕ_2), and Receiver (ϕ_R); the Phase of the Proton 180° Pulse in Sequence (4) is Immaterial

ϕ_1	0321	1032	2103	3210
ϕ_2	0000	1111	2222	3333
ϕ_R	0123	1230	2301	3012

both homonuclear and proton flip heteronuclear *J*-resolved spectra. More complex experiments such as semiselective *J* spectroscopy^{21,22} can be simulated by replacing T^{IS} with the matrix representation of a BIRD operator.²⁰

4 APPLICATIONS

4.1 Practical Implementation

J-resolved spectroscopy is one of the easiest 2D methods to implement. Sequences (2) and (3) require only the usual calibration of the 90° observe pulse width, which is not critical; if α is the actual flip angle of a nominal 90° pulse, the signal obtained is proportional to $\sin \alpha \cos 2\alpha$. Calibration of the proton 180° pulse in sequence (3) can be carried out by setting t_1 equal to $1/J(\text{C,H})$ and varying the proton pulse width; the signal is nulled when the flip angle is 90°, and inverted when it is 180°. For all three basic sequences the phases

Figure 3 300 MHz proton spectra of sucrose octaacetate. From right to left: normal 1D spectrum; *J*-resolved spectrum; tilted *J*-resolved spectrum; and f_2 projection of the tilted *J*-resolved spectrum

of the 90° pulse, 180° refocusing pulse, and receiver should follow a scheme such as that in Table 1, which combines EXORCYCLE¹⁴ and CYCLOPS.²⁸

The two principal advantages of *J*-resolved spectroscopy are the decrease in f_1 linewidth afforded by suppressing B_0 inhomogeneity effects, and the improved ability to distinguish signals that results from separating multiplet structure from chemical shifts. The former advantage is generally restricted to small molecules with long T_2 s, and is most commonly exploited in ^1H – ^{13}C heteronuclear *J*-resolved spectroscopy, while the latter is most useful in ^1H homonuclear *J*-resolved spectroscopy.

4.2 Homonuclear *J*-Resolved 2D spectroscopy

Figure 3 shows the sugar ring region of the 300 MHz proton spectra of a solution of sucrose octaacetate in deuteriochloroform. At the right is the normal 1D spectrum, together with a contour plot of the *J*-resolved spectrum. Pseudoecho weighting was used, with absolute value display; good results are also achievable with sine-bell weighting. Strong coupling signals are visible, for example in the region around 5.4 ppm, in addition to the expected multiplets. The effects of ‘tilting’ the data matrix at 45° in frequency space

Figure 4 Gated decoupler heteronuclear *J*-resolved ^{13}C spectrum of cholesteryl acetate, showing a stacked trace plot of an expanded region

are illustrated in the left-hand contour plot of Figure 3, which shows the J -resolved spectrum after applying equation (1). At the far left of Figure 3, the results of integrating or 'projecting' the tilted spectrum along the f_1 direction to give a 'proton-decoupled proton' spectrum are shown; again, strong coupling artifacts are visible, for example around 5.4 ppm.

4.3 Heteronuclear J -Resolved 2D Spectroscopy

The two classical uses of heteronuclear J -resolved spectroscopy are with low f_1 resolution for the determination of multiplicity, and with high f_1 resolution for the measurement of long-range ^1H - ^{13}C couplings in small molecules. DEPT is now generally preferred for multiplicity determination, but J -resolved spectroscopy remains the method of choice for high-resolution measurements of $^nJ(\text{C},\text{H})$. One advantage of heteronuclear J -resolved spectroscopy for multiplicity determination is that it gives clear results in the presence of ^{13}C shift degeneracy: Figure 4 shows a contour plot of a gated decoupler spectrum of a solution of cholesteryl acetate in deuterochloroform, together with an expanded stacked trace plot of an overlapping region, showing the coincidence of a methine and a methylene signal at about 29 ppm.

4.4 Semiselective J -Resolved 2D Spectroscopy

Figure 5 shows experimental and theoretical cross sections through a high-resolution heteronuclear semiselective 2D J

Figure 5 Semiselective one-bond suppressed heteronuclear J -resolved ^{13}C spectra for C-2 of thiophene (60% v/v solution in deuteroacetone): (top) calculated and (bottom) experimental. The sequence of Bax²¹ was used, on a 400 MHz spectrometer

spectrum of thiophene in acetone- d_6 . One-bond couplings have been suppressed by choosing phases 0, 0, and 180° for the three successive proton pulses of the BIRD sequence.²⁰ The cross sections illustrate both the high resolution achievable and the complexity of the spectra that can result even from relatively small strongly coupled spin systems. The theoretical trace was calculated using the approach outlined in Section 3.2;²² the delays during the BIRD sequence allow some of the strong coupling responses to appear in dispersion mode.

1 INTRODUCTION

There are two general motivations to measure the ^{13}C chemical shift tensor in a solid. The first is that it is sensitive to the electronic structure of the molecule in the vicinity of the nucleus, and therefore provides useful experimental data for testing theoretical models of molecular electronic structure. The second, more practical, motivation is analytic in nature; the chemical shift tensor is a sensitive and often unique tool for characterizing heterogeneous materials, and its orientational dependence can be exploited to help characterize partially oriented materials.

The measurement of the ^{13}C chemical shift tensor's principal values and its orientation with respect to the molecular coordinate system is often difficult. A common method is to rotate a single crystal of the sample in a magnetic field and map the relationship between the field direction and the resonance frequency for each magnetically equivalent carbon nucleus in the sample.¹ As the number of magnetically unique carbon nuclei in the crystal increases, correlated 2D exchange NMR spectroscopy is a powerful tool in resolving and correlating the peaks resulting from similar chemical shift tensors.^{1,2}

When a good single crystal of the sample is not available, powder techniques must be used. In simple cases, the principal values may be measured from the breakpoints of a 1D powder pattern. The powder spectrum is then simulated with a chemical shift powder pattern for each unique carbon in the sample in order to measure the principal values. This technique is limited to relatively simple spectra, owing to the complexity of fitting multiple, overlapping 1D powder patterns. There are a number of alternate experimental approaches to solving this problem, many of which are reviewed elsewhere in this Encyclopedia.

A relatively simple 2D technique for measuring principal values of overlapping ^{13}C chemical shift tensor patterns in powders is the chemical shift–chemical shift correlation experiment developed for single crystal measurements.^{2–4} The sample is rotated relative to the external magnetic field during the mixing time of a 2D exchange experiment, which correlates the powder patterns in the two different orientations. The resulting 2D powder patterns have a characteristic shape that

depends on the angle of the rotation and the principal values of the chemical shift tensors in the sample. This method utilizes the additional resolution available in 2D spectroscopy, and is especially useful for sorting the principal values of chemical shift tensors in badly overlapped 1D powder patterns.

2 EXPERIMENTAL

The probe appropriate for the 2D powder correlation experiment is a double tuned, large-sample-volume system designed to allow ^1H decoupling and rapid 90° rotation of the sample about an axis perpendicular to the external magnetic field, as shown in Figure 1. The results reported here were obtained using a Bruker CXP-200 NMR spectrometer, with a resonance frequency of 50.3 MHz for ^{13}C .

The pulse sequence used in the experiment is shown in Figure 2. The first part of the pulse sequence is the common cross-polarization technique with Hartmann–Hahn matching and spin locking between the ^1H and ^{13}C spins. The remainder of the sequence is a chemical exchange experiment that correlates two different ^{13}C chemical shift evolutions. Here, ν and w are the phases of the ^1H rf pulses, and x and Φ_i those of the ^{13}C pulses. In this experiment, the measured chemical shift is determined solely by the orientation of the crystallite in the magnetic field. The sample is rotated by 90° during the mixing time, so each crystallite in the powdered sample ‘sees’ two different magnetic field directions during t_1 and t_2 , which results in two different evolution frequencies ω_1 and ω_2 . The resulting 2D powder patterns contain information about all of the ^{13}C chemical shift tensors in the sample, and are characteristic of the 90° sample rotation.

Figure 1 90° sample reorientation apparatus. The powdered sample is placed in a shortened 12 mm NMR tube, which is then epoxied into the sample pulley. The pulley is rotated inside a circular recess in the housing by pulling the attached string

Figure 2 Chemical shift–chemical shift correlation pulse sequence. Phase cycling corrects for artifacts resulting from ^{13}C T_1 relaxation during the mixing time and cross polarization during the 180° echo pulse, and allows for quadrature detection during the evolution dimension. The mixing period is 35 ms long

The 2D data are gathered according to the prescription of States, Haberkorn, and Ruben,⁵ which gives amplitude-modulated hypercomplex multidimensional data sets.

3 RESULTS

The spectrum in Figure 3 is a contour plot of the 2D chemical shift correlation spectrum of ferrocene, with the more familiar 1D projections of the spectrum shown at the sides. Ferrocene has an axially symmetric ^{13}C chemical shift tensor whose orientation is determined by its motion about the molecular rotational axis; $\delta_{\parallel}$ is the principal value of the chemical shift tensor when the field is parallel to ferrocene's rotational axis, and $\delta_{\perp}$ is the degenerate principal value when the field lies parallel to the ring plane. An axially symmetric 2D powder pattern has three large peaks connected by ridges forming a right isosceles triangular pattern with a deep basin in its interior. Comparing the features of the 2D spectrum with its 1D projections indicates that the peaks or cusps define the principal values of the chemical shift tensor.

The ferrocene spectrum is a simple example of a 2D chemical shift correlation pattern. The principal values could have been obtained equally well from a 1D powder spectrum. The 2D technique is significantly more useful when multiple overlapping bands in a 1D powder spectrum leave unresolvable ambiguities. The spectrum of coronene shown in Figure 4 illustrates how powerful the 2D correlation technique is. Coronene has three sets of unique carbons, and the molecule rapidly rotates about an axis perpendicular to its plane, averaging all of its chemical shift tensors to axial symmetry. The foremost challenge in measuring the principal values of the three coronene tensors from the 1D powder spectrum was to determine which pairs of the six breakpoints are grouped together as the principal values for each of the three different ^{13}C nuclei in the molecule. The spectrum in Figure 4 exhibits how these groupings were readily determined with the 2D chemical shift correlation experiment. The correlative properties of the powder pattern allows immediate

Figure 3 Equal-amplitude contour plot of the 2D ^{13}C chemical shift–chemical shift correlation experimental spectrum of ferrocene (dicyclopentadienyliron). The scales are in ppm from liquid TMS (positive values are to high frequency). ω_1 is the vertical dimension and ω_2 is the horizontal dimension. The diameter of the small circle plotted in the upper right-hand corner is the full width at halfheight of the Gaussian broadening ($\Delta\omega_G$) function that is convolved with the data. In this figure, $\Delta\omega_G = 3$ ppm. The 1D powder projections are plotted on the vertical and horizontal axes

connection of principal value pairs from each chemically distinct nucleus.

The 2D chemical shift correlation spectrum of isotactic polypropylene is shown in Figure 5. This spectrum indicates that the added correlation and resolution of two dimensions resolves three different chemical shift tensor patterns in a situation where the 1D powder pattern is intractable.

Figure 4 Contour plot of the spectrum of coronene (hexabenzobenzene). The Gaussian broadening in this figure is 3 ppm

Figure 5 Contour plot of the spectrum of isotactic polypropylene. The Gaussian broadening in this figure is approximately 2.5 ppm

In an effort to determine the limits of resolution of this technique, a spectrum of methyl α -D-glucopyranoside was acquired (Figure 6). Methyl α -D-glucopyranoside has seven carbon types, whose severely overlapped ^{13}C chemical shift tensors have been measured in a single crystal, and therefore is an excellent candidate for comparison of techniques. The 1D powder spectrum is severely overlapped, with almost no distinguishable features to facilitate conventional fitting techniques. However, the 2D powder pattern does show a considerable improvement in resolution. At least four distinct powder patterns may be immediately recognized by the

Figure 6 Contour plot of the spectrum of methyl α -D-glucopyranoside

outlines of the cliff-like features that form the boundaries of the patterns. This spectrum was simulated by successively subtracting out simulated components from the pattern and finding new component patterns in the residual spectrum. Prior knowledge of the tensor principal values was not used. The results of this fitting agree well with previous results,⁶ as shown in Figure 7. Although this fitting technique left two possible shift tensors unresolved, one of the simulated component patterns has roughly twice the integrated amplitude of the remaining five patterns, indicating that the two unresolved tensor patterns have very similar principal values, which could not be reliably distinguished with this analysis technique.

The measurement of six of the seven ^{13}C chemical shift tensor principal values in methyl α -D-glucopyranoside represents a remarkable increase in resolution over 1D powder spectroscopy, and perhaps an upper limit on the number of overlapping powder patterns that can be successfully resolved with the 2D chemical shift correlation technique. The agreement between the single crystal data and the powder fitting data is very good.

The increased resolving power of the chemical shift correlation experiment has been applied to complex samples such as coals in order to measure the aromaticity of the sample. Figure 8 shows the spectrum of the Argonne premium coal, Pocahontas #3. This spectrum has a clear segregation of amplitude between two different regions. The small volume in the upper right-hand corner of the spectrum has a relatively narrow chemical shift anisotropy and an average chemical shift of approximately 25 ppm. These chemical shifts fall into a range expected from aliphatic carbon nuclei; therefore, this volume represents the aliphatic fraction of the sample. The triangular shaped volume in the lower left-hand corner of this spectrum has a broader chemical shift anisotropy, and an average chemical shift of approximately 130 ppm, and represents the aromatic fraction of the sample. The ratio of these two volumes gives an estimate of the sample's aromaticity:

$$\% \text{ Aromaticity} = \frac{\text{Volume}_{\text{aromatic}}}{\text{Volume}_{\text{aromatic}} + \text{Volume}_{\text{aliphatic}}} \times 100\% \quad (1)$$

Figure 7 Chemical shift tensor principal values of methyl α -D-glucopyranoside. The bold lines indicate values measured in a single crystal experiment.⁶ The lighter faced lines indicate values measured from fitting the 2D powder spectrum. The dashed lines indicate the values of the average chemical shift, i.e., $\delta_{\text{average}} = \frac{1}{3} (\delta_{11} + \delta_{22} + \delta_{33})$

Figure 8 Contour plot of the spectrum of the Argonne premium coal, Pocahontas #3. The Gaussian broadening in this figure is approximately 20 ppm

This quantity has been measured from the spectrum in Figure 8, and the result is 87%. There is good agreement between the aromaticity measured from these data and the more conventional CP MAS result of 86%. An advantage of the chemical shift correlation technique is that it is less sensitive to the Hartmann–Hahn matching condition than is the CP MAS technique. This data also has the potential

for testing theoretical models that attempt to correlate the components of the chemical structure of coals and related materials with the distributions of chemical shift anisotropy.

4 SIMULATIONS

In order briefly to establish the correspondence between the principal values of the chemical shift tensor and the features of 2D chemical shift correlation spectra, a series of computer simulations for the 90° sample rotation experiment representing the different classes of chemical shift tensors are shown in Figure 9. The general triangular or hexagonal shape of the simulations is a characteristic of the 90° sample rotation experiment. These simulations show the relationships between the ridges and peaks of this new type of 2D spectrum and the breakpoints in the 1D powder spectra, which are plotted as projections below the 2D simulations.

Often, the measurement of principal values from 1D powder patterns is seriously hindered by nonideal distribution of amplitude across the spectrum, especially when cross-polarization techniques are used. The ability to simulate this amplitude distortion in a 2D powder pattern would increase the accuracy of the measurement of principal values. The frequency and amplitude of the NMR signal from a particular nucleus in a given crystallite in a powdered sample is determined by the principal values of its chemical shift tensor and by that crystallite's orientation relative to the external magnetic field. Therefore, the simulation model is parameterized in terms of chemical shift tensor principal values and the three Euler orientation angles α , β , and γ that describe the relative orientation of the nuclear environment with the external magnetic field in a randomly oriented powder.

Figure 9 Contour plots of 2D 90° sample rotation simulations resulting from five different chemical shift tensors, showing the correspondence between the features in the 2D powder patterns and conventional 1D powder patterns: (a) axially symmetric chemical shift tensor with low-frequency (upfield) degenerate principal values; (b) general chemical shift tensor with $\delta_{11} - \delta_{22} = 3(\delta_{22} - \delta_{33})$; (c) general chemical shift tensor with $\delta_{11} - \delta_{22} = \delta_{22} - \delta_{33}$; (d) general chemical shift tensor with $3(\delta_{11} - \delta_{22}) = \delta_{22} - \delta_{33}$; (e) axially symmetric chemical shift tensor with high-frequency degenerate principal values

In this experiment, each nucleus in the sample has two resonance frequencies, which correspond to the two different orientations that the nucleus may have with the external field during t_1 and t_2 . Assuming a random distribution of crystallite orientations, the simulated hypercomplex 2D FID from a single nucleus in an experiment where the external field is along the x sample axis during t_1 and along the y sample axis during t_2 can be written as

$$s_{\text{sim}}(t_1, t_2) = \frac{1}{8\pi^2} \int d\alpha \sin \beta d\beta d\gamma A(\alpha, \beta, \gamma) \times \left[\exp\{i_1[\omega_x(\alpha, \beta, \gamma) - \omega_0]t_1\} \exp\left(-\frac{t_1^2 \Delta\omega_{G1}^2}{G^2}\right) \right] \times \left[\exp\{i_2[\omega_y(\alpha, \beta, \gamma) - \omega_0]t_2\} \exp\left(-\frac{t_2^2 \Delta\omega_{G2}^2}{G^2}\right) \right] \quad (2)$$

where $A(\alpha, \beta, \gamma)$ is an amplitude weighting function that depends upon the crystallite orientation in the field. The frequency ω_0 is the spectrometer carrier frequency, and $\Delta\omega_{G1}$ and $\Delta\omega_{G2}$ are Gaussian broadenings in the t_1 and t_2 dimensions, respectively. G^2 is a constant equal to $4 \ln(2)/\pi^2$. The imaginary units i_1 and i_2 (with $i_1^2 = i_2^2 = -1$) distinguish the independent imaginary parts of the hypercomplex t_1 and t_2 data.⁷ The resonance frequencies for the x and y field directions of a given crystallite with an α, β, γ orientation

relative to the principal axis frame of the tensor are given by the matrix products

$$\left. \begin{aligned} \omega_x(\alpha, \beta, \gamma) &= \mathbf{x}^{-1} \mathbf{R}^{-1}(\alpha, \beta, \gamma) \delta \mathbf{R}(\alpha, \beta, \gamma) \mathbf{x} \\ \omega_y(\alpha, \beta, \gamma) &= \mathbf{y}^{-1} \mathbf{R}^{-1}(\alpha, \beta, \gamma) \delta \mathbf{R}(\alpha, \beta, \gamma) \mathbf{y} \end{aligned} \right\} \quad (3)$$

where $\mathbf{x}$ and $\mathbf{y}$ are unit column vectors in the x and y sample frame directions, respectively. The unitary rotation matrix $\mathbf{R}(\alpha, \beta, \gamma)$ rotates the chemical shift tensor δ from its principal axis frame to the sample frame, and this tensor in the principal axis frame is

$$\delta = \begin{bmatrix} \delta_{11} & 0 & 0 \\ 0 & \delta_{22} & 0 \\ 0 & 0 & \delta_{33} \end{bmatrix} \quad (4)$$

Nonideal amplitude distributions in powder spectra are primarily artifacts resulting from the orientational dependence of both cross polarization and spin relaxation. Functions of orientation described by the Euler angles α, β , and γ are conveniently expanded in the Wigner rotation matrices $\mathcal{D}_{m',m}^{(j)}(\alpha, \beta, \gamma)$, which form a complete, orthonormal basis set.^{8,9} The three-dimensional amplitude weighting function that accounts for the polarization efficiency can be expanded as

$$A(\alpha, \beta, \gamma) = \sum_{j,m',m} a_{m',m}^{(j)} \mathcal{D}_{m',m}^{(j)}(\alpha, \beta, \gamma) \quad (5)$$

where the j sum is from 0 to ∞ and the m and m' sums run from $-j$ to $+j$. The expansion coefficients $a_{m',m}^{(j)}$ thus provide a complete description of the different amplitudes resulting from all possible crystallite orientations. The mathematical construct of Equation (5) can also be used to characterize ordering in partially oriented samples.

It can be shown that the simulated 2D FID may be expanded in a complete set of Wigner 2D subFIDs, where the linear coefficients $a_{m',m}^{(j)}$ are the weighting factors for each of the orthonormal Wigner subFIDs $s_{m',m}^{(j)}(t_1, t_2)$ in the basis set

$$s_{\text{sim}}(t_1, t_2) = \sum_{j,m',m} a_{m',m}^{(j)} s_{m',m}^{(j)}(t_1, t_2) \quad (6)$$

These functions can be used to determine any general amplitude distribution in the spectrum using standard linear fitting techniques.

Although all of the fitting is done in the time domain, the 2D Fourier transform of the 2D FID produces the more familiar simulated 2D spectra:⁷

$$S(\omega_1, \omega_2) = \int_{-\infty}^{+\infty} dt_1 \exp(-i_1 \omega t_1) \times \int_{-\infty}^{+\infty} dt_2 \exp(-i_2 \omega t_2) s(t_1, t_2) \quad (7)$$

Likewise, the Fourier transforms of the subFIDs give the subspectra:¹⁰

$$S_{m',m}^{(j)}(\omega_1, \omega_2) = \int_{-\infty}^{+\infty} dt_1 \exp(-i_1 \omega t_1) \times \int_{-\infty}^{+\infty} dt_2 \exp(-i_2 \omega t_2) s_{m',m}^{(j)}(t_1, t_2) \quad (8)$$

The first subspectrum in the series, $S_{0,0}^0$, is the 'ideal' powder spectrum. This subspectrum represents the case where each

spin in the sample contributes the same amplitude to the spectrum, and where every crystallite orientation is equally probable. This term is also the only member of the expansion whose integrated spectrum has a nonzero volume. The higher order subspectra in the series are positive in some areas and negative in others, so that they integrate to zero volume over the domain of the spectrum. These higher order subFIDs or subspectra describe modifications in the spectral amplitude that deviate from the ‘ideal’ powder response, and may be used to characterize the orientational dependence of the amplitude that results either from experimental artifacts or from macroscopically ordered samples. It has been found for most powder spectra that the number of terms necessary to simulate effectively all of the deficiencies in the spectrum is relatively small, indicating that $A(\alpha, \beta, \gamma)$ is a fairly smooth function in α , β , and γ . It has also been found for the 2D powder spectra presented here that the coefficient $a_{0,0}^0$ is much larger than the higher order coefficients, supporting the general observation that the amplitude distribution across a powder pattern is nearly ideal, with only relatively small nonideal contributions.

5 DISCUSSION

The chemical shift tensor principal values reported here result from fitting simulations calculated from Equation (6) to the data. The fitting is done in the time domain, where the fractional residual is taken as the figure of merit for any

given simulation, and is minimized to find the ‘best fit’. The fractional residual is defined as

$$\text{fractional residual} = \frac{\sum_{t_1, t_2} |s_{\text{data}}(t_1, t_2) - k s_{\text{sim}}(t_1, t_2)|^2}{\sum_{t_1, t_2} |s_{\text{data}}(t_1, t_2)|^2} \quad (9)$$

where $s_{\text{data}}(t_1, t_2)$ is the 2D hypercomplex data FID, and k is a scaling constant that adjusts for experimental factors in the acquisition and processing of the data.

The ‘best fit’ results for ferrocene, coronene, polyethylene, and polypropylene given in Table 1 are in excellent agreement with previous results.^{11–14} The chemical shift principal values differ by 3 ppm or less from the values measured with other techniques, while the average chemical shifts i.e., $\delta_{\text{average}} = \frac{1}{3}(\delta_{11} + \delta_{22} + \delta_{33})$ differ from published CP MAS isotropic chemical shifts by 1 ppm or less.

This 2D technique has some distinct advantages over other methods for measuring ^{13}C shift tensor principal values in complex powdered solids. The inherent correlation and resolution advantage of 2D powder spectroscopy over conventional 1D techniques is evident in the spectra of coronene, polypropylene, methyl α -D-glucopyranoside, and coal. Powder patterns that overlap severely in 1D spectra can often be untangled with this 2D spectroscopy. Another powerful advantage of the technique is that the data can be simulated and fit with a high degree of fidelity using a straightforward physical model.

Another significant advantage of the technique is its simplicity. The sample does not spin at high speeds at the

magic angle; therefore, the probe can be designed to accept a larger volume sample inside a transverse solenoidal coil in order to optimize sensitivity. The 90° rotation of the sample is not difficult to accomplish accurately, both in terms of constructing and driving the mechanism. The sample is stationary during the cross-polarization time, which results in more effective Hartmann–Hahn matching. The principal values of the chemical shift are represented in frequencies measured from the spectrum, not from information encoded in spinning sideband amplitudes, as in slow spinning techniques. Furthermore, the frequencies of the principal values of the chemical shift tensors are measured directly from the spectra; there is no scaling factor relating the frequencies measured in the spectrum to the principal values of the chemical shift tensor.

1 INTRODUCTION

NMR is not only the most detailed probe of molecular structure and dynamics with the highest spectral resolution, it is also the basis for MRI. Nonetheless, an ever-present drawback of NMR, due to the low transition frequency, is a requirement for large amounts of sample, containing at least 10^{15} – 10^{16} spins. Therefore, the suggestion by Sidles¹ that it might be possible to use force to detect and image the nuclear resonance of a single proton was remarkable. His idea was to effect three-way resonant coupling among (1) a precessing proton mounted on (2) a vibrating substrate and (3) a mechanical oscillator holding a magnetic particle which produces both a dc field and a strong magnetic field gradient. The proton exerts a force on the mechanical oscillator through interaction with the magnetic field gradient generated by the particle. Energy transfer into the oscillator, mediated via the magnetic force between the proton and oscillator, is sufficient that single-proton detection is possible by sensing excitation of the mechanical oscillator.

Sidles also carried out a quantum mechanical analysis of his proposal,² showing the resemblance to a Stern–Gerlach experiment³ in the sense that the linear trajectory of the spins in the latter becomes folded into the cyclic phase-space trajectory of the oscillator on which the gradient source is mounted. Sidles et al.⁴ have comprehensively discussed the physics of oscillator-coupled imaging, while Sidles and Rugar⁵ have compared the sensitivity of force and inductive methods of detection and have concluded that the former is a viable alternative to the latter as size is reduced to dimensions of the order of tens of nanometers. The first experimental force detection of magnetic resonance was achieved by Rugar et al.,⁶ who used a modified magnetic force microscope⁷ to detect electron spin resonance (ESR). A key feature of their approach was to modulate the ESR condition at low

frequency in order to overcome the gap between the Larmor frequency of electron spins, normally in the gigahertz range, and the kilohertz frequencies of mechanical cantilevers used for atomic or magnetic force microscopy. Subsequently, Züger and Rugar^{8,9} were able to obtain ESR images demonstrating spatial resolution of about $1\mu\text{m}$. Most recently, Rugar et al. made the first successful force detection of NMR with subfemtonewton force sensitivity.¹⁰ Based on these results and the near-theoretical performance of their force probe, they estimated that it should be possible to detect a single proton at temperatures of about 1 K.

Sidles and Garbini¹¹ have reviewed the current status of magnetic resonance force microscopy, and have concluded that the use of a submicrometer size gradient source, coupled with interferometric detection methods,^{12,13} make single-spin detection with a magnetic resonance force microscope (MRFM) a realistic possibility. Bloom¹⁴ has analyzed Sidles's proposed single-spin-imaging idea in the light of Stern–Gerlach phenomenology,¹⁵ and more recently, Leskowitz and Weitekamp¹⁶ have suggested a method for doing force-detected NMR spectroscopy using rf gradients. In the present article the principles underlying magnetic resonance force detection and microscopy, as well as the ESR and NMR experiments are reviewed.^{16a} A brief discussion of the feasibility of imaging a single proton is also given.

The appeal of single-spin NMR is compelling. Single-nucleus magnetic resonance with subangstrom spatial resolution would revolutionize the determination of molecular structure, and myriad significant applications could lead to breakthroughs in materials science as well as in the biological sciences. Even at much lower levels of spatial resolution (of the order of tens to hundreds of angstroms), MRFM would signify a quantum leap in the imaging power of magnetic resonance microscopy.

2 PRINCIPLES OF MAGNETIC RESONANCE FORCE MICROSCOPY

The force detected in MRFM is given by

$$\mathbf{F} = (\mathbf{m} \cdot \nabla)\mathbf{B} \quad (1)$$

where $\mathbf{m}$ is a magnetic moment due to electron or nuclear spins, and $\mathbf{B}$ is an inhomogeneous magnetic field. The spin magnetic moment is $\mathbf{m} = \mathbf{M}V$, where $\mathbf{M}$ is the Curie spin magnetization and V is the sample volume. $\mathbf{M}$ is given by¹⁷

$$\mathbf{M} = N\gamma^2\hbar^2 I(I+1)\mathbf{B}/3k_{\text{B}}T \quad (2)$$

where N is the number of spins per unit volume, γ is the spin magnetogyric ratio, I is the nuclear spin quantum number, and k_{B} is Boltzmann's constant. A sketch of a probe for doing force-detected magnetic resonance is shown in Figure 1.

The apparatus resembles a magnetic force microscope⁷ with the addition of a millimeter-size rf coil mounted close to the sample. The coil provides an oscillating field to excite magnetic resonance. In the absence of rf excitation, the force on the spin magnetization of the sample, mounted on the cantilever, in the field gradient generated by the nearby magnetic particle

Figure 1 Basic configuration of a magnetic resonance force microscope. The force on the sample magnetization in the gradient of a proximate magnetic field source causes a deflection of the cantilever which is sensed optically. The rf coil is used to excite spin resonance

causes a deflection of the cantilever which is sensed by a fiber-optic interferometer.^{12,13} If the spin magnetization is changed, then the force and corresponding cantilever deflection will be changed and sensed. Magnetic resonance techniques can be used to manipulate the spin magnetization by applying an rf field. The device sensitivity can be increased considerably by changing the sample magnetization at the same frequency as the mechanical resonance frequency of the cantilever.⁴ The cantilever deflection amplitude is then enhanced by the quality factor of the cantilever, and the resulting vibration amplitude is

$$A = Q(F/k) \quad (3)$$

where Q is the quality factor, and k the spring constant of the cantilever. The deflection signal is synchronously detected at the cantilever frequency using a lock-in amplifier and experiments are carried out in modest vacuum (about 0.133–0.0133 Pa) in order to avoid air damping of the cantilever motion which would result in a low Q . Typical Q values of cantilevers used for atomic force microscopy (AFM)¹⁸ in vacuo are 10^3 to 10^5 . The kilohertz resonance frequency and high Q result in time constants of the order of seconds. Since this corresponds to the time it takes to build up to the cantilever amplitude given by equation (3), the low-frequency spin motion required to change the spin magnetization at the cantilever frequency should be sustained for a correspondingly long time. In existing devices, sensitivity of the MRFM is limited mainly by thermal noise, manifested as a fluctuating force acting on the cantilever:^{4,19,20}

$$F_{\min} = (4kk_B T \Delta\nu / Q\omega_c)^{1/2} \quad (4)$$

where ω_c is the cantilever frequency and $\Delta\nu$ is the detection bandwidth in hertz. The minimum detectable magnetic moment in the presence of thermal noise is therefore given by:

$$m_{\min} = F_{\min} / |\nabla B| \quad (5)$$

This moment sets a lower limit on the number of spins that can be detected.

3 EXPERIMENTAL RESULTS

3.1 Electron Spin Resonance

The first successful force detection of magnetic resonance was carried out on a sample containing unpaired electron spins.⁵ A micrometer-size sample of diphenylpicrylhydrazyl (DPPH) was mounted on a silicon nitride cantilever of the type commonly used for atomic force microscopy.²¹ The cantilever was $200\mu\text{m}$ long and $0.7\mu\text{m}$ thick, with a force constant $k = 0.1\text{ N m}^{-1}$. The frequency of the loaded cantilever was 8 kHz and Q was 2000. The experiment was done at room temperature in a vacuum of about 0.133 Pa. The gradient source, which generated a field gradient of 10 T m^{-1} at the sample, was a cylindrical NdFeB permanent magnet, 3 mm long and 3 mm diameter. A continuous wave 220 MHz rf field was applied to the spins via a millimeter-size coil positioned about 1 mm from the sample. A small electromagnet was used to scan and modulate the dc field.

3.1.1 Cyclic Saturation

As noted above, detection sensitivity is enhanced if the spin magnetization is made to oscillate at the resonance frequency of the cantilever. This was accomplished by means of a cyclic saturation technique,²² which is illustrated in Figure 2. To understand the technique, it is useful to consider the behavior of the longitudinal magnetization when the sample is subjected to an rf field B_1 , which is linearly polarized in a direction perpendicular to the dc field B_z . This case has been investigated theoretically.²³ Figure 2(a) shows M_z as a function of

Figure 2 (a) The behavior of longitudinal magnetization (M_z) under the influence of an rf field in the presence of relaxation. The field modulation shown is used to change the resonance condition at the cantilever frequency and to excite the cantilever. M_z is suppressed when the resonance condition is met. (b) The second harmonic response resulting from modulation of the resonance condition effected by field modulation

an externally applied field, the resultant of the field from the electromagnet and proximate NdFeB magnet. The effect of the 220 MHz rf field is to saturate the spin levels at resonance, $B_z = \pm 7.9$ mT, driving M_z to zero. The low-frequency force modulation necessary to enhance deflection of the cantilever [equation (3)] can thus be achieved by cyclic saturation, i.e. by modulating the amplitude of the electron spin magnetization. This was accomplished by modulating the dc field in and out of resonance. When the modulation amplitude is zero, the field is on resonance and $M_z = 0$, due to saturation by the rf field, while off resonance, M_z will recover if the electron spin–lattice relaxation time T_{1e} is sufficiently short. Since T_{1e} in DPPH²² is 6.2×10^{-8} s and the modulation period is much longer (2.5×10^{-4} s for a 4 kHz modulation frequency), M_z recovers fully when the modulation moves the field off resonance. Furthermore, M_z goes to zero twice during each modulation cycle, resulting in the second harmonic response (M_2) shown in Figure 2(b). Therefore, modulation of B_z at 4 kHz excites the cantilever at its resonance frequency (8 kHz), thus minimizing on-resonance feed-through problems that arise when the modulation frequency is 8 kHz. This process can be continued indefinitely due to the short electron spin T_{1e} , thus giving the cantilever ample time to build up a large deflection amplitude.

3.1.2 Force Detection of ESR

Figure 3(a) shows the vibration amplitude of the cantilever on which the DPPH sample was mounted as the dc field was scanned and modulated at 4 kHz. The peaks in the cantilever oscillation amplitude occurred when the ESR condition was met. The 0.28 nm cantilever vibration corresponds to an oscillatory driving force of only 10^{-14} N. Figure 3(b) shows a calculation of the second harmonic response, M_2 , using known experimental parameters. The modulation field used was 1 mT (zero to peak), and the rf field strength, obtained from the simulation, was 3.4 mT. The change in cantilever frequency due to sample loading indicated that approximately 15 ng of DPPH, corresponding to 2×10^{13} electron spins, contributed to the signal. The good agreement between experiment and theory is evident in Figure 3.

The gradient used to obtain the data shown in Figure 3(a) was 10 T m^{-1} . When this was increased to 60 T m^{-1} by using a smaller magnetic particle, two resonance lines spaced 1.1 mT apart were resolved, suggesting that there may be two spatially separated DPPH particles, an idea confirmed upon inspection with an optical microscope. This spectral separation corresponded to a distance of $19 \mu\text{m}$. The fact that such high spatial resolution was obtained in the first force detection experiment illustrates the imaging potential of force detection of magnetic resonance.

3.1.3 Force-Detected ESR Microscopy

The first MRFM images were obtained by Züger and Rugar^{8,9} on micrometer-size particles of DPPH. An optical micrograph of critical components of the probe, similar to that used for the ESR experiment, is shown in Figure 4. The spring constant of the silicon nitride cantilever²⁴ was $k = 0.05 \text{ N m}^{-1}$ and the rf coil (0.7 mm diameter, 2.5 turns), located 0.5 mm from the sample, was tunable from 800 to 1610 MHz. The magnetic field gradient source, a conical NdFeB permanent

Figure 3 (a) Amplitude of cantilever vibration as the polarizing field is scanned through the ESR condition for DPPH. The field was modulated at 4 kHz with a zero-to-peak amplitude of 1 mT. The data shown are the average of 54 sweeps, each lasting 20 s. The time constant of the lock-in amplifier was 0.3 s. (b) Calculation of the second-harmonic response of the magnetization induced by modulation of the ESR of DPPH. The only parameter that was not known was the strength of the rf field, chosen to be 3.4 mT on the basis of the best fit with the data in (a)

magnet (0.5 mm diameter, 1 mm long) was mounted on a piezoelectric translator to allow mechanical scanning in any of three dimensions relative to the sample (mounted on the cantilever). Figure 5(a) shows a surface of constant (resonance) field $B_i(x, y, z) = B_0$ generated by such a tip. The imaging behavior of the MRFM can be understood by moving a point sample in the xy plane perpendicular to the symmetry axis z of the tip. Since the B_0 surface approximates a paraboloid the apex of which is located along the axis of the tip, intersection of the sample with such a surface results in force mapping of a circle of resonance responses. The diameter of the circle depends on the distance from the tip to the sample along the symmetry axis of the tip (z coordinate). This behavior,

Figure 4 Optical micrograph of key components of the force probe developed by Züger and Rugar^{8,9} for ESR imaging. f, Optical fiber of the interferometer; c, rf coil; t, permanent magnet tip (dark region); s, DPPH sample glued on the cantilever

Figure 5 (a) Dashed lines, showing the magnetic field lines from a conical-shaped magnetic tip used for ESR force imaging. The surface of constant field strength is a paraboloid near the axis of the tip, and the circles indicate where the magnetic resonance condition is met on the surface $B = B_0$ as the tip is scanned in the xy plane at a fixed sample distance z from the tip. (b) Measured force maps for a small DPPH particle scanned in the xy plane at three different distances from the tip: $z_0 \approx 200 \mu\text{m}$, $z_1 = z_0 - 3 \mu\text{m}$, and $z_2 = z_0 - 8 \mu\text{m}$. The gray scale represents cantilever vibration amplitude, with white representing maximum amplitude. The image size is $200 \mu\text{m} \times 200 \mu\text{m}$

sketched in Figure 5(a) for three different values of z , has been confirmed experimentally, as shown in Figure 5(b). If the tip is at z_0 , resonance only occurs at the apex of the paraboloid, resulting in a single-point response, while at distances closer to the tip force mapping traces out circles of resonance which get larger as the tip is approached. These results permitted a quantitative characterization of the tip field, from which a point-response function, the oscillatory force per spin as a function of position, can be determined. This function can then be used to reconstruct the spatial distribution of spin density from the force map of a three-dimensional sample.

The success of this approach is illustrated in Figure 6, which shows the results of a two-dimensional ESR force mapping of the unpaired electron spin density in two micrometer-size particles of DPPH. An optical micrograph of the sample mounted on the cantilever [Figure 6(a)] shows that the particles are about $20 \mu\text{m}$ wide and are separated by $35 \mu\text{m}$. An ESR force map of this sample, taken at a distance from the tip of about $124 \mu\text{m}$, is shown in Figure 6(b). Two resonance circles with slightly different diameter and radial thickness were obtained. The diameter difference is due to a small difference in the z position of the particles, while a difference in lateral particle size accounts for the difference in circle thickness. An image-reconstruction technique using inverse filtering resulted in the spin density image shown in Figure 6(c). The ESR image shows two spin density maxima $35 \mu\text{m}$ apart, in agreement with the optical micrograph. Even the triangular shape of the lower particle in Figure 5(a) is reproduced in the reconstructed

(a) Sample

(b) Force map

(c) Reconstructed image

50 μm

Figure 6 (a) Optical micrograph showing two DPPH particles (about $20 \mu\text{m}$ wide) attached to a silicon nitride cantilever. The distance between particles is about $35 \mu\text{m}$. (b) Magnetic resonance force map of the sample measured at a distance of $z = z_0 - 6 \approx 124 \mu\text{m}$. The data shown consist of a 128×128 pixel array which was acquired during a 90-min scan. (c) Reconstructed spin density image obtained by deconvolving the data in (b) using a Wiener filter. The two bright features correspond to the two DPPH particles. The large rings slightly visible in the image are artifacts of the deconvolution procedure

image. The extension of this method to three dimensions using a set of force maps measured at different values of z is straightforward.

An estimate of the resolution of the MRFM used in this experiment was obtained from a knowledge of the ESR linewidth and the axial and lateral gradients characterizing the magnetic tip. The spatial resolution in the z direction was determined to be about $1 \mu\text{m}$, a factor of at least 5 greater than the resolution achieved using conventional ESR imaging methods.^{25,26} The resolution in the lateral xy direction was estimated to be $5.3 \mu\text{m}$. An analysis of the signal-to-noise ratio indicated that 10^9 electron spins could be detected. Thus, even in these early experiments, force detection was quite sensitive, being comparable to 140 GHz high-field ESR.²⁷

3.2 NMR

3.2.1 Challenges

Force detection of NMR, which was recently reported,¹⁰ presented a greater challenge than ESR for two reasons: (1) the magnetic moment of, and corresponding force exerted by, any nucleus is about 10^3 times less than for electron spins (657 times less for protons); and (2) nuclear spin–lattice relaxation times are typically 10^6 times longer than the electron spin T_{1e} , and thus the cyclic saturation method used in the ESR experiment will not work. In order to meet these challenges, three steps were taken: (1) ultrathin cantilevers which yielded subfemtonewton force sensitivity were fabricated;²⁰ (2) the experiment was carried out at higher magnetic field (2.4 T) to increase the nuclear magnetization which interacts with the gradient source; and (3) the required low-frequency force modulation was produced by means of cyclic adiabatic inversion, a method which can be used periodically to invert the direction of the nuclear magnetic moment.²⁸

3.2.2 Custom-Fabricated Cantilevers

A micrograph of the silicon nitride cantilever which was custom-fabricated by Hoen et al.²⁰ is shown in Figure 7. This cantilever, which is considerably smaller than the one used for the ESR experiment,⁶ has a stem $50\ \mu\text{m}$ long and $5\ \mu\text{m}$ wide which supports a $30\ \mu\text{m} \times 30\ \mu\text{m}$ paddle. The proton-containing sample, 14 ng of ammonium nitrate, was mounted on this paddle using UV-curable epoxy glue. The cantilever is only 90 nm thick, resulting in a spring constant of $10^{-3}\ \text{N m}^{-1}$, at least 30 times smaller than for typical AFM cantilevers. The force sensitivity, to our knowledge the highest reported to date, was found²⁰ to be $5 \times 10^{-16}\ \text{N}$. The frequency of the loaded cantilever was 1.4 kHz with an intrinsic Q value of 3000.

3.2.3 Cyclic Adiabatic Inversion

Cyclic adiabatic inversion is a CW NMR method which works well with nuclei that have long spin–lattice relaxation times.²⁸ Since nuclear magnetization is not only conserved but reversed in sign during an adiabatic passage, the force created between the magnetization and a gradient source will oscillate sinusoidally. Therefore, subjecting the nuclear spins to a prolonged sequence of cyclic adiabatic reversals will generate the low-frequency spin motion required to enhance the cantilever deflection amplitude. The inversion was accomplished by using the frequency modulation scheme shown in Figure 8(a).

Before the rf field is turned on, the rf frequency is set 500 kHz (several linewidths) below resonance, as shown in Figure 8(a). After allowing time for the nuclei to polarize (dashed lines), the rf amplitude is turned up, creating an effective field in the rotating frame.²⁹

$$\mathbf{B}_{\text{eff}} = B_1 \hat{x} + (B_z - \omega/\gamma) \hat{z} \quad (6)$$

where ω is the radiofrequency. Since the frequency is far below resonance, the proton magnetization $\mathbf{M}_0$ becomes locked along an effective field³⁰ parallel to $\mathbf{B}_0$ so that the longitudinal component M_z has a maximum positive value [Figure 8(b)].

- $k = 10^{-3}\ \text{N/m}$
- $Q = 3000$ in vacuum
- $5 \times 10^{-16}\ \text{N}/\sqrt{\text{Hz}}$ force sensitivity at 300 K.

Figure 7 Optical micrograph of the 90 nm thick silicon nitride cantilever. A small grain of the sample (ammonium nitrate) is visible on the upper portion of the paddle-shaped cantilever. The narrow stem of the cantilever is $50\ \mu\text{m}$ long and $5\ \mu\text{m}$ wide. The cantilever was fabricated by S. Hoen, IBM Almaden Research Center

M_z is of interest since the deflection of the cantilever is along the z direction, i.e. the relevant force is

$$F_z = M_z V (\partial B_z / \partial z) \quad (7)$$

where V is the sample volume. The frequency is then slewed onto resonance sufficiently slowly that the adiabatic condition is satisfied:³¹

$$|d\mathbf{B}_{\text{eff}}/dt| \ll \gamma_H B_1^2 \quad (8)$$

where γ_H is the proton magnetogyric ratio. The direction of $\mathbf{M}_0$ follows the direction of the effective field²⁹ and M_z decreases to zero as the rf approaches the resonance value. As the frequency sweep is continued through resonance, M_z becomes negative. At the most positive frequency excursion, M_z reaches a maximum negative value. The modulation is then continued as shown in Figure 8(a) and the resulting time-dependent longitudinal magnetization (Figure 8(b)) makes the force on the sample cyclic and causes the cantilever to vibrate at its resonance frequency. This process is continued as long as the amplitude of the magnetization does not decay so much that the oscillating force becomes too small for the cantilever to be excited. The proton magnetization decays in two ways: (1) violation of the adiabatic condition, and (2) a short relaxation time in the rotating frame ($T_{1\rho}$).³⁰ The adiabatic condition can

Figure 8 (a) Frequency modulation pattern used for cyclic adiabatic inversion. The dashed lines indicate time (>4 s) that is used to allow the nuclei to polarize with the rf field off. A single modulation cycle lasts about 1 ms, and in the actual experiment is repeated several thousand times. (b) Time dependence of M_z resulting from the frequency modulation shown in (a)

be satisfied readily since the rf and modulation field strengths can be varied independently (the modulation frequency is fixed at the cantilever frequency). Decay due to rotating-frame relaxation depends primarily upon the presence of low-frequency lattice motions,³² and in this respect ammonium nitrate is a favorable material since the protons have a long $T_{1\rho}$ (about 2 s) at room temperature.^{33,34} Since this was a first attempt at force detection of NMR, a comprehensive study of the spin dynamics in bulk ammonium nitrate was carried out³⁴ to ensure that the proton magnetization would (1) follow the behavior sketched in Figure 8(b) and (2) not decay too quickly while subject to the irradiation shown in Figure 8(a). The parameters used to achieve cyclic adiabatic reversal in the force experiment were guided by the results of this study.

3.2.4 Force Detection and Imaging of NMR

The gradient source in this experiment was a magnetizable iron cylinder (1.5 mm diameter, 4 mm long) mounted on a piezoelectric translator. In an external field of 1.95 T, the iron cylinder produced an additional field of 0.4 T when positioned 700 μm from the sample, resulting in a total field of 2.35 T and a proton resonance frequency of 100 MHz. The gradient at the sample was 600 T m^{-1} . The experiment was carried out at room temperature in a vacuum of about 0.0133 Pa.

In order to locate the resonance, the dc field was scanned by moving the gradient source relative to the sample/cantilever. Each time the position of the source was changed, the sample was allowed to polarize for about 4 s before the rf was turned on and the frequency modulated as shown. The rf field (1.5 mT at 100 MHz) was generated in a coil 800 μm

Figure 9 Amplitude of the cantilever vibration as the magnetized particle is moved relative to the ammonium nitrate sample, scanning the field through the ^1H resonance. At each discrete position of the particle, indicated by the plateaus, the modulation sequence shown in Figure 8(a) is applied to the sample and the peak cantilever vibration amplitude was measured. The rms force noise is about 5×10^{-16} N

in diameter positioned 700 μm from the sample and was frequency modulated with a deviation of 170 kHz (4 mT) at the cantilever frequency (1.4 kHz). The angstrom-scale motion of the cantilever was monitored optically^{12,13} and the signal synchronously detected using a lock-in amplifier. The result of a 60 mT (100 μm) scan is shown in Figure 9, in which the vibration amplitude of the cantilever is plotted as a function of the position of the gradient source. The plateaus along the horizontal represent discrete positions of the gradient source, corresponding to discrete values of the field at the sample. The cantilever deflection amplitude reached a maximum of 160 Å (16 nm) at the field strength where the proton resonance condition was met with a single-scan root-mean-square (rms) signal-to-noise ratio of 22. Since the sample contained 3.6×10^{14} protons, the minimum detectable number of protons (a signal-to-noise ratio of unity) was 1.6×10^{13} . The response was confirmed as arising from NMR by changing the rf frequency and locating the maximum in the cantilever response at different positions of the gradient source. The magnetic field gradient of 600 T m^{-1} was also measured using this procedure.

The imaging capability of the MRFM was characterized by performing rapid (5 s) scans of the modulated carrier frequency. The result is shown in Figure 10. The gradient source was fixed, so that different z slices of the sample experienced different dc fields and came into resonance as the rf field swept through the Larmor frequency corresponding to those slices. The plot of cantilever amplitude (force) is thus a plot of proton spin density in the z direction perpendicular to the plane of the paddle (see Figure 7). The strength of the rf and modulation fields was decreased in order to achieve the highest possible spatial resolution. Furthermore, the cantilever was damped to shorten the response time,³⁵ resulting in an effective Q of 800. The frequency range over which the cantilever responded was 240 kHz, corresponding to a sample thickness of about 9 μm . The width between the 10% and 90% amplitude points at the steepest part of the response (the back side of the sample mounted to the cantilever) was $\Delta f = 67$ kHz, corresponding to a spatial resolution of $\Delta z = 2\pi \Delta f$

Figure 10 One-dimensional image of proton density in a 12-ng sample of ammonium nitrate, obtained by measuring the cantilever vibration amplitude as a function of the carrier frequency. The 640 kHz frequency range was scanned in 5 s with the rf field on continuously and frequency modulated. The signal-to-noise ratio was improved by averaging 120 scans. The length of the $5\ \mu\text{m}$ bar is based on the $600\ \text{T m}^{-1}$ gradient over the sample. The $2.6\text{-}\mu\text{m}$ spatial resolution was estimated from the width of 67 kHz between the 10% and 90% amplitude points on the right-hand edge of the spin density profile. The measurement conditions were: $B_1 = 0.83\ \text{mT}$, modulation deviation (zero-to-peak) = 25 kHz, and effective cantilever $Q = 800$

$(\gamma\partial B_z/\partial z) = 2.6\ \mu\text{m}$. This resolution is roughly an order of magnitude greater than has been achieved using conventional NMR microscopy on nonmetallic solid samples.³⁶

4 DETECTING THE NMR OF A SINGLE PROTON

The remarkable sensitivity of force detection in the experiments performed to date^{6,8,10} coupled with the good agreement between the calculated and experimental performance of the force detection apparatus, permits a realistic quantitative assessment of the possibility of detecting a single proton using force methods. One approach for judging the feasibility of doing this is to note that it was possible to detect the force on 1.6×10^{13} proton magnetic moments in a gradient of $600\ \text{T m}^{-1}$. The actual moment interacting with the gradient is not given by the total number of protons in the sample, but by the excess number in the state with lower Zeeman energy:

$$N = N_H(\hbar\gamma_H B_0/2k_B T) \quad (9)$$

where N_H is the total number of protons, and the Boltzmann factor (in parentheses) is about 10^{-5} for a 2.5 T field at ambient temperature. Therefore, only 10^8 proton moments interacted with the gradient and provided the force in the NMR experiment. Thus, the improvement in sensitivity that is required for single-proton detection is 10^8 rather than 10^{13} . Another way of looking at this is to recognize that a single proton is always fully ‘polarized’, while ensembles of protons are subject to the cancellation of moments inherent in a Boltzmann population of spin states of opposite polarity. The factor of 10^8 improvement in sensitivity can be gained by a combination of higher field gradients, lower temperatures, and improved cantilevers.

A factor of 10^5 in signal strength/spin can be obtained by using a much stronger gradient source. Magnetic tips with

a radius of curvature of 30 nm have been fabricated³⁷ and would generate gradients of $10^8\ \text{T m}^{-1}$. This is 10^5 times greater than the gradient used in the first NMR force-detection experiment,¹⁰ yielding a force/spin and concomitant signal 5 orders of magnitude larger.

Another order of magnitude in sensitivity can be gained by operating at 1 K, resulting in a 10-fold reduction in the force noise due to thermal fluctuations [equation (4)]. Further reduction in force noise can be realized if softer, higher Q cantilevers can be fabricated. For example, it should be feasible to make a silicon nitride cantilever $50\ \mu\text{m}$ long, $2\ \mu\text{m}$ wide and 20 nm thick. The force constant for such a ‘diving board’ structure would be $5 \times 10^{-6}\ \text{N m}^{-1}$ with a resonance frequency of 10 kHz and a Q of 10^4 . These characteristics lead to another 2 orders of magnitude increase in force sensitivity. Hoen et al.²⁰ have already shown that it is possible to fabricate ultrathin cantilevers with these dimensions. Compounding these improvements leads to an overall increase in sensitivity of 10^8 , making single-proton imaging realistic.

5 SUMMARY AND CONCLUSIONS

The idea of using force to detect magnetic resonance¹ has been realized experimentally for NMR¹⁰ and ESR,⁶ with exceptional sensitivity in both instances. Furthermore, the first ESR images from a magnetic resonance force microscope have been obtained with high spatial resolution.^{8,9} The theoretical basis for force-detected single-spin imaging has also been investigated, without evidence for violation of any fundamental physical principles.^{2,4,14} The ultimate goal of this work is to develop an instrument that can detect NMR from individual atoms within a sample with three-dimensional subangstrom spatial resolution. Such a capability would allow visualization of the three-dimensional structure of molecules and would represent a revolutionary advance in magnetic resonance imaging. Furthermore, because of its subsurface imaging potential and elemental specificity, MRFM would take a major step beyond the capabilities of present-day scanning tunneling and atomic force microscopies. The availability of an atomic MRFM would have broad implications in molecular biology, materials and polymer science, surface science, and nanotechnology.

Achieving the ultimate goal of three-dimensional atomic-scale imaging will be challenging and technically demanding, and will require considerable innovation in a number of areas, especially improved sensors to detect extremely small forces and new methods for manipulating nuclear spins. Despite the enormity of the challenge, the practical applications of single-spin MRFM imaging are sufficiently important, and the results to date sufficiently encouraging, that a serious and sustained MRFM development effort is justified.

1 INTRODUCTION

1.1 Motivation

The physical mechanism of nuclear magnetic resonance spectroscopy, the excitation of transitions between nuclear spin states, was explored in the years after World War II, and is by now well characterized. Today's interest in the field is based largely on the immense potential for applications: spins can serve as probes for their environment because they are weakly coupled to other degrees of freedom. In most magnetic resonance experiments, these couplings are used to monitor the environment of the nuclei, like spatial structures or molecular dynamics. While the direct excitation of nuclear spin transitions requires irradiation with a radiofrequency field, many systems offer the alternative possibility of using light for polarizing the spin system or for observing its dynamics. This possibility arises from the coupling between the spins and the electronic degrees of freedom: optical photons excite transitions between states that differ both in electronic excitation energy as well as in their angular momentum states.

The light can serve three different purposes: it can polarize the spin system, thereby creating the 'raw material' for spectroscopic experiments; it can measure the spin polarization, serving as a detector; and it can influence the dynamics of the system. Some motivations for using light in magnetic resonance experiments include the following:

Sensitivity. In many cases, the possible sensitivity gains are the primary reason for using optical methods. Compared to conventional NMR, sensitivity gains of more than 10 orders of magnitude are possible. Thus so far, two groups have demonstrated the magnetic resonance of individual molecules,^{1,2} while a typical NMR sample contains of the order of 10^{20} spins.

Selectivity. Using lasers, it is possible to observe selectively signals from certain regions in space, such as surfaces. Alternatively, a laser pulse may define the time of an observation with a resolution of 10^{-14} s or select a particular chemical environment like the chromophore of a molecule or a quantum well in a semiconductor. Crystal imperfections can change the optical properties of an atomic or molecular site in

such a way that optical excitation can distinguish those sites against a background that is orders of magnitude larger.

Speed. Conventional magnetic resonance requires the presence of population differences between spin states to excite transitions between them. In most cases, thermal relaxation establishes these population differences. At low temperatures, this coupling process may be too slow for magnetic resonance experiments. In the case of optical excitation, a polarizing laser beam creates the population differences. The time required for polarization of the system then depends only on the laser intensity and can be instantaneous on the timescale of the magnetic resonance experiment, independent of temperature.

Experiments in electronically excited states. If information about an electronically excited state that is not populated in thermal equilibrium is desired, it may be necessary to use light to populate this state. It is then certainly advantageous to populate the different spin states unequally to obtain at the same time the polarization differences that are needed to excite and observe spin transitions.

1.2 Laser Spectroscopy

Apart from magnetic resonance, the interaction of matter with laser light is the second most important ingredient for the experiments that will be discussed below. In laser spectroscopy, light induces transitions between different electronic states. Many of the differences between laser spectroscopy and magnetic resonance arise from the different frequency scales: optical frequencies are more than six orders of magnitude higher than rf frequencies. An important consequence is that laser spectroscopy is much more sensitive as a technique: optical experiments on individual atoms^{3,4} and molecules^{5,6} have become routine in the last few years. While the first experiments of this type used atomic ions in ultrahigh vacuum, they can now also be performed in condensed matter, like solutions⁵ or solid matrices.⁶

Another attractive feature of laser spectroscopy is the high time resolution, which is of course also intimately linked to the high frequencies of optical radiation. Technical limits to the time resolution are now of the order of a few femtoseconds, corresponding to only a few optical cycles. In chemistry, this resolution allows 'real time' monitoring of chemical reactions, e.g. by measuring the intermolecular potential as a function of time during the reaction. Also in solid state physics, laser spectroscopy allows the monitoring of fast processes, such as the excitation and recombination of electrons and holes in semiconductors.

In the field of high-resolution spectroscopy, it is also possible to achieve very high frequency resolution: some systems can now reach resolutions of better than 1 Hz, corresponding to a relative frequency stability of some 10^{15} . This high-frequency resolution is especially attractive for metrology, where many groups are trying to build new, more precise frequency standards based on optical transitions. These properties of laser spectroscopy, high-frequency resolution and high temporal resolution open attractive possibilities for applications in optically enhanced magnetic resonance experiments.

The next section discusses the most important physical phenomena that permit the use of laser radiation in magnetic resonance experiments. Examples of applications to specific systems are discussed in the third section.

2 PHYSICAL BACKGROUND

2.1 Angular Momentum

The possibility of using optical radiation for exciting and detecting spin polarization can be traced to the angular momentum of the photon. Photons as carriers of the electromagnetic interaction carry one unit ($\hbar$) of angular momentum, which is oriented parallel or antiparallel to the direction of light propagation. Since angular momentum is a conserved quantity, the total angular momentum of the system (radiation and matter) remains constant during absorption and emission of radiation. When an atom or molecule absorbs a photon, it must incorporate not only the photon energy but also its angular momentum (see Figure 1). The resulting angular momentum of the atom is the vector sum of its initial angular momentum plus the angular momentum of the absorbed photon.

Figure 1 Conservation of angular momentum during absorption of a photon

Magnetic resonance spectroscopy requires a spin polarization inside the medium. In conventional magnetic resonance experiments, thermal contact of the spins with the lattice establishes this polarization. This process is relatively slow, especially at low temperatures where relaxation times can be many hours. The polarizations are limited by the Boltzmann factor, which is typically less than 10^{-5} . Photon angular momentum, in contrast, can be created in arbitrary quantities with a polarization that can be arbitrarily close to unity. If it is possible to transfer this polarization to nuclear or electronic spins, their polarization can reach the same values.

2.2 Optical Pumping

This possibility was first suggested by Kastler.^{7,8} Figure 2 illustrates the principle of operation. The model atomic system consists of two electronic states, labelled $|g\rangle$ for ground state and $|e\rangle$ for excited state. We assume that both have an angular momentum $J = \frac{1}{2}$; their angular momentum substates are labeled as $J_z = +\frac{1}{2}$ and $J_z = -\frac{1}{2}$ in the figure. If the system is irradiated by circularly polarized light, the photons have a spin quantum number $m_s = +1$. Since the absorption of a photon is possible only if both the energy and the angular momentum of the system are conserved, only those ground state atoms that are initially in the $J_z = -\frac{1}{2}$ state can absorb photons. If an atom is initially in the state $J_z = +\frac{1}{2}$, the resulting excited

Figure 2 Principle of optical pumping illustrated for a simple atomic system

state would have to be a $J_z = +\frac{3}{2}$ state, which does not exist in the atom of our model system.

An atom that has absorbed a photon will re-emit one after the excited state lifetime. Spontaneous emission can occur in an arbitrary direction in space and is therefore not subject to the same selection rules as the excitation process with a laser beam of definite direction of propagation. The spontaneously emitted photons carry away angular momentum with different orientations and the atom can therefore end up in either of the two ground states. If it ends up in the original state, it can absorb another photon and repeat the cycle; if it ends up in the other state, it no longer couples to the laser field and remains in this state indefinitely. The net effect of the absorption and emission processes is therefore a transfer of population from one spin state to the other and thereby a polarization of the atomic system.

2.3 Dynamics

As in conventional magnetic resonance, the spin polarization undergoes Larmor precession in an external magnetic field. If we use light to drive the spin system, it also affects the spin dynamics: if the laser couples to a particular transition, it appears to shift the energy of the levels to which it couples.^{9,10} Shifts of energy levels always affect the dynamics of the corresponding system. In this case, the energy level shift has exactly the same effect as a magnetic field parallel to the direction of the laser beam. The light shift effects are therefore often analyzed in terms of virtual magnetic fields. The strength of this virtual magnetic field depends on the detuning of the laser from the electronic transition frequency. Besides these level shifts, the laser light also causes a damping of the spin polarization. In contrast to the light shift effect, which has a dispersive dependence on the laser detuning, the damping effect has an absorptive behavior, i.e. its maximum occurs when the laser frequency is exactly resonant with the optical transition frequency. Light shift and damping are the main contributors to laser-induced dynamics in atomic spin systems.¹¹

Figure 3 Principle of observation of spin polarization by optical radiation

2.4 Observation

The last requirement for optically enhanced magnetic resonance is a method for observing the spin polarization. An early suggestion that magnetic resonance transitions should be observable in optical experiments is due to Bitter.¹² The physical process used in such experiments is the complement of optical pumping: it transfers spin angular momentum to the photons and polarization-selective detection measures the photon angular momentum. Figure 3 illustrates this for the same model system that we considered for optical pumping. Light with a given circular polarization interacts only with one of the ground state sublevels. Since the absorption of the medium is directly proportional to the number of atoms that interact with the light, a comparison of the absorption of the medium for the two opposite circular polarizations yields the population difference between the two spin states directly. This population difference is directly proportional to the component of the magnetization parallel to the laser beam. This analysis of the transmitted light allows the observation of spin polarization in the electronic ground state. Another possibility is the analysis of the fluorescence light: angular momentum conservation imposes correlations between the direction and polarization of the spontaneously emitted photons, which depend on the angular momentum state of the excited atom.

As shown schematically in Figure 4, the difference between the atomic angular momentum of the excited and ground states determines the angular momentum J_v of the spontaneously emitted photon. This condition determines the polarization of the emitted radiation for a given direction. In the first experiments on optical pumping, observation of the fluorescence allowed not only the measurement of the excited state polarization, but also the ground state polarization to be inferred.¹³

Figure 4 Polarization of the fluorescence depends on the spin state of the excited atoms

Figure 5 Summary of the most important reservoirs of angular momentum

2.5 Angular Momentum Reservoirs

Atoms and molecules may contain different types of angular momentum. The most important reservoirs include the rotational motion of molecules, the orbital angular momentum of electrons, and the spin angular momentum of electrons and nuclei. Not all these types of angular momentum couple directly to the radiation field: in free atoms, only the orbital angular momentum of the electrons is directly coupled to the optical transitions. However, various interactions couple the different types of angular momentum to each other and allow the polarization to flow from the photon spin reservoir through the electron orbital to all the other reservoirs, as shown schematically in Figure 5. This is, of course, of spatial interest for nuclear magnetic resonance, since there is no direct transfer to nuclear spins. However, the coupling between electronic and nuclear angular momentum is usually strong enough to provide an efficient transfer mechanism. This even allows the polarization of nuclear spin systems in diamagnetic ground states.

In the example of Figure 6, the electronic ground state is diamagnetic and has a nuclear spin $I = \frac{1}{2}$. Since the nuclear spin does not affect the absorption of light, both spin states interact with a circularly polarized laser beam. Angular momentum conservation requires that optical excitation populates only the states with an electronic angular momentum of $m_J = 1$. If electronic and nuclear spin are parallel in the excited state ($m_J = 1, m_I = \frac{1}{2}$, dashed line in Figure 6), the resulting state does not evolve until it reemits a photon and decays into the state from which it was excited. If, however, the nuclear spin is oriented antiparallel to the electronic angular momentum ($m_J = 1, m_I = -\frac{1}{2}$), the hyperfine interaction can induce simultaneous spin flips that conserve the total angular momentum and transfer the atom into the ($m_J = 0, m_I = \frac{1}{2}$) state. Spontaneous decay from this state again leaves the nuclear spin unchanged and thus brings the

Figure 6 Polarization of nuclear spin reservoirs in diamagnetic ground states

atom into the $m_I = +\frac{1}{2}$ ground state. The net effect of the absorption–hyperfine–emission cycle is therefore the transfer of an atom from the $-\frac{1}{2}$ to the $+\frac{1}{2}$ nuclear spin state. A sequence of such cycles polarizes the nuclear spin system in complete analogy to the case of electronic spin polarization.

Spin polarization can be transferred between different reservoirs, not only within one atomic species but also between different particles. This was first demonstrated by Dehmelt who used transfer to free electrons to polarize them.¹⁴ Another frequently used transfer process includes optical pumping of alkali atoms, in particular Rb and Cs, and the transfer of their spin polarization to noble gas atoms like Xe. This method was pioneered by Happer et al.¹⁵ and applied to the study of surfaces in systems with high surface to volume ratios like graphitized carbon¹⁶ or to the construction of NMR gyroscopes.^{17,18} The transfer from alkali to noble gas atoms is relatively efficient because they form van der Waals complexes. During the lifetime of this quasi-molecule, the dipole–dipole interaction between the two spins induces simultaneous flips of the two spin species, which transfer polarization from the Rb atoms to the Xe nuclear spin. Typical cross-polarization times are on the order of minutes, but the long lifetime of the Xe polarization permits reaching polarizations close to unity. The spin polarization survives freezing¹⁹ and can be transferred to other spins by thermal mixing.²⁰

At low magnetic fields, the coupling between the reservoirs can exceed the Zeeman interaction between the individual spins and the magnetic field. This implies that the spins do not evolve independently, but as a collective entity that may include electronic as well as nuclear spins. Under these conditions, the traditional distinction between ESR and NMR loses its meaning: electronic and nuclear spins undergo simultaneous transitions. Nevertheless, it may be possible to extract the different physical parameters for the various interactions. Figure 7 shows an example: in Na atoms, the hyperfine interaction couples the electron ($S = \frac{1}{2}$) and nuclear spins ($I = \frac{3}{2}$) with a coupling constant of 1.8 GHz. In fields less than 0.1 T, the hyperfine interaction is therefore significantly stronger than the Zeeman interaction. For the spectrum shown here, the atoms were placed in a field of 0.7 mT. At these field strengths the two spins remain strongly coupled but, as shown in the spectrum, the electron Zeeman interaction can be determined as 5 MHz and the nuclear Zeeman interaction as 19 kHz.

Figure 7 Example of an optically detected magnetic resonance spectrum in a strongly coupled system

Figure 8 Principle of laser magnetic resonance

2.6 Laser Magnetic Resonance

A method for the optical detection of magnetic resonance transitions that does not directly rely on the conservation of angular momentum is laser magnetic resonance. It uses transitions between states that differ both in their electronic or vibrational and angular momentum quantum numbers. Transitions between such states depend on magnetic interactions but fall into the optical frequency range. The population difference between the two states is thus close to unity and the detection of the radiation is highly efficient.

Figure 8 illustrates the principle of the method: a magnetic field lifts the degeneracy of both the ground and excited states. For the figure, only a single spin $I = \frac{1}{2}$ was assumed. If the laser induces transitions that change both the vibrational and the spin quantum number, such as the transitions indicated by arrows in Figure 8, the resonance frequency depends clearly on the magnetic field strength. The resulting spectra contain the information about the magnetic interactions in both the excited and the ground state. Experiments of this type were performed in molecular gases²¹ as well as in semiconductor materials, where the process is known as spin-flip Raman scattering.^{22,23}

While this method allows high sensitivity, its resolution is lower than with direct detection. In most experimental settings, the laser linewidth limits the resolution. Optical rf double resonance methods²⁴ or a modification of the basic Raman experiment that is known as coherent Raman scattering can overcome this limitation.

2.7 Coherent Raman Processes

Raman processes can be considered as an interaction between two optical photons and a material excitation, as shown schematically in Figure 9. The arrows labeled ω_1 , ω_2 represent two optical fields that couple to two allowed optical transitions that share the energy level |3⟩. If two laser fields with these frequencies are incident on the three-level system, they excite coherences in all three transitions of the three-level system, in particular also the coherence labeled ω_{12} in the transition that is not directly coupled to the laser fields. If, conversely, the coherence in transition |1⟩ ↔ |2⟩ is already present in the material, and a single laser field at frequency ω_1 is incident on the system, it excites a Raman field at frequency $\omega_2 = \omega_1 + \omega_{12}$. This Raman field propagates with the incident laser field and the frequency ω_{12} can be measured as the difference between the two optical frequencies. If the laser frequency drifts, the frequency of the incident field as well

Figure 9 Raman processes couple two electromagnetic fields (ω_1 , ω_2) with a material excitation

as that of the Raman field changes by the same amount. As a result, the difference frequency is unchanged and the resolution of the measurement is not affected by laser frequency jitter or broad optical resonance lines.²⁵ Coherent Raman processes therefore provide a combination of high resolution with high sensitivity.

The implementation of coherent Raman scattering must somehow create the coherent excitation of the material. This can be achieved either with optical fields^{26–28} or with radiofrequency irradiation.²⁹

2.8 Sensitivity

Several mechanisms contribute to the increase in sensitivity by optical methods. The first is the spin polarization that can be achieved. If thermal relaxation establishes the spin polarization, it cannot exceed the Boltzmann factor which is at most on the order of 10^{-5} . Optically, it is possible to polarize the spins completely and thereby gain some five orders of magnitude.³⁰ In addition, the optical detection process occurs at much higher energies: optical photons have energies some seven orders of magnitude higher than that of rf photons. Detecting a small number of optical photons is therefore significantly easier than detection of rf photons. At the same time, thermal noise is almost negligible at optical frequencies. A third reason for the increased sensitivity is that laser irradiation can polarize the spins much faster: depending primarily on the laser intensity, complete polarization of the spin system may require less than $1 \mu\text{s}$.³¹

Since optical detection directly measures the magnetization, in contrast to pick-up coils that measure its time-derivative, the detection sensitivity is independent of the resonance frequency. It is therefore possible to perform experiments at low or vanishing fields with the same detection efficiency as at high fields. This is of particular interest in cases where one wants to measure small effects like rotational velocities, which cannot be seen in high fields.³²

2.9 Information Content

Apart from the advantage of sensitivity, optically enhanced magnetic resonance is sometimes capable of providing information which conventional methods cannot provide. We illustrate this with the measurement of the sign of the nuclear

Figure 10 Principle of the measurement of nuclear quadrupole interaction by laser spectroscopy

quadrupole interaction. The nonspherical part of the charge distribution of atomic nuclei with spin $I > \frac{1}{2}$ is a sensitive probe of the electric field at the site of the nucleus. Measurements of the interaction between the nuclear quadrupole moment and the electric field gradient (EFG) tensor can provide information about the electronic and structural environment of the nuclei, as well as about motional processes. Many experiments in magnetic resonance are therefore performed to measure quadrupole couplings.³³ However, conventional magnetic resonance experiments cannot provide the sign of the coupling.³⁴

In the simplest case of axial symmetry, the Hamiltonian $\hat{\mathcal{H}}_Q$ of the nuclear quadrupole interaction is given by a coupling constant D multiplied by the square of the nuclear spin operator $\hat{I}_Z$, $\hat{\mathcal{H}}_Q = D\hat{I}_Z^2$. The coupling constant D is determined by the size of the nuclear quadrupole moment and the electric field gradient. It can be measured either without a magnetic field, which corresponds to the case of pure quadrupole coupling, or in a high magnetic field, which corresponds to the case of high-field NMR. In both cases, the spectra are identical for positive and negative sign of the coupling constant D .

Figure 10 schematically shows how laser spectroscopy can be used to measure the nuclear quadrupole interaction with the sign information. In the model system considered here, the spin is $\frac{5}{2}$ and a measurement is performed in zero magnetic field. In the electronic ground state, the system then has three sets of doubly degenerate states. If we can neglect the quadrupole splitting in the excited state, as assumed in Figure 10, the absorption spectrum directly provides the splittings between the levels. Reversal of the sign of the quadrupole splitting leads to a reversal of the line positions in the spectrum (Figure 11). In actual systems, the inhomogeneous broadening of the optical resonance lines complicates the procedure. Closely analogous measurements are nevertheless possible and have allowed the measurement of the quadrupole coupling constant of Pr^{3+} in the host material YAlO_3 as shown in Figure 11.³⁵

3 APPLICATIONS

It is of course impossible to give a complete summary of the large number of applications that have used optically enhanced magnetic resonance techniques in various systems. The present selection tries to demonstrate the wide range of systems for

Figure 11 Comparison of the experimental spectrum (top) with theoretical stick spectra for negative and positive quadrupole coupling

which optical methods can be used, but also in addition the various ways in which optical radiation can enhance magnetic resonance spectroscopy.

3.1 Dielectric Solids

Optical pumping and optical detection of magnetic resonance transitions were first demonstrated in atomic vapors^{8,13} but soon afterwards also in ionic solids.^{36,37} Ruby ($\text{Cr}^{3+}:\text{Al}_2\text{O}_3$) proved an ideal test material, as it has relatively narrow optical absorption lines and allows different methods of optical pumping. Most experiments reported to date have been performed with inorganic ionic solids, in particular rare earth and transition metal compounds. The experimental techniques used for these studies include purely optical methods such as photon echo modulation^{38,39} and coherent Raman beats,⁴⁰ as well as double resonance methods such as Raman heterodyne spectroscopy.⁴¹

We start the discussion with an example for a purely optical method that combines several attractive features: while its sensitivity is that of an optical method, its resolution is not limited by laser jitter or optical dephasing, but only by the natural linewidth. Furthermore, it yields magnetic resonance spectra from an electronically excited as well as from the ground state. The material system that we consider here consists of the rare earth ion $^{141}\text{Pr}^{3+}$ with a nuclear spin $I = \frac{5}{2}$. The ions are substituted into the host material of YAlO_3 , where they occupy the Y sites with a doping concentration of 0.1%. In zero magnetic field, the interaction between the nuclear quadrupole moment and the electric field gradient (EFG) tensor lifts the degeneracy of the nuclear spin states of ^{141}Pr ; the interaction with the quenched electronic spin enhances the quadrupole coupling as well as the nuclear Zeeman interaction.

The experimental scheme uses Raman processes for exciting the nuclear spin transitions as well as for observing the spin precession. A laser pulse that couples to two optical transitions sharing a common energy level excites a coherence in the third transition of the three-level system, as explained above. The excitation pulse should not be longer than the spontaneous lifetime of the electronic state. For the $^1\text{D}_2$ state of Pr^{3+} , this limits the duration of the laser pulses to $\tau_P < 100 \mu\text{s}$. After the pulse, the coherence is allowed to precess freely and a second,

Figure 12 Example of NQR spectra obtained by purely optical excitation and detection of nuclear spin coherence. Both spectra were combined from three partial spectra which were recorded with different modulation frequencies in order to reduce distortion due to finite excitation range

weaker laser beam is used to observe the precession, again using a Raman process. The condition for efficient excitation of the sublevel coherence is that the difference between the two frequency components of the exciting laser pulse is close to the sublevel transition frequency.²⁸ For the observation process, the laser frequency must be close to one of the two optical transition frequencies. The signal that is observed after the optical pulse can be Fourier-transformed to recover the usual NMR/NQR spectrum.

Figure 12 shows two examples of spectra that were measured with this method. They represent nuclear spin transitions of the electronic ground state and an electronically excited state of $\text{Pr}^{3+}:\text{YAlO}_3$. For both states, not only the magnetic dipole allowed transitions ($\pm\frac{1}{2} \leftrightarrow \pm\frac{3}{2}$, $\pm\frac{3}{2} \leftrightarrow \pm\frac{5}{2}$) are visible, but also the double quantum transition ($\pm\frac{1}{2} \leftrightarrow \pm\frac{5}{2}$), indicating that the selection rules of conventional magnetic resonance do not apply to Raman-detected magnetic resonance. The quadrupole interaction strength differs significantly for excited and ground state (0.9 MHz versus 7 MHz). As with magnetically excited spectra, the bandwidth of the excitation process is limited. In this case, the transition strength is quite low. With a laser power of 20 mW, it was possible to excite subspectra with a width of approximately 1 MHz. To reduce the distortions associated with the excitation of considerably wider spectra, we therefore combined three subspectra containing one resonance line each. The width of the resonance lines is determined by spin-diffusion of the dipole-dipole interaction with the neighboring Al nuclei.

Excitation of magnetic resonance transitions with radiofrequency irradiation relies on the conversion of longitudinal into transverse magnetization; an experiment can therefore start only after thermal relaxation has established population differences by coupling to the lattice. At low temperatures, this process can be very slow in rigid solids. Optical excitation, in contrast, converts population differences between different electronic states into transverse magnetization. Spontaneous emission establishes these population differences on a very short timescale (nanoseconds to femtoseconds), independent of temperature. As a result, purely optical experiments do not require long relaxation delays and allow fast repetition rates.

Figure 13 Raman heterodyne spectrum of $\text{Pr}^{3+}:\text{YAlO}_3$ in a weak magnetic field

Raman experiments do not have to use only optical techniques. Double resonance techniques that include optical as well as rf irradiation have been used successfully. The rf field establishes a coherence in a magnetic resonance transition, and the same Raman process that we discussed above detects it. In such an experiment, the laser beam serves a threefold purpose: it establishes a population difference, which the rf field converts into transverse magnetization. The same⁴¹ or a second³⁵ laser beam partially converts the precessing magnetization into optical polarization by a coherent Raman process, and as a third function, the laser beam serves as the local oscillator for the detection of the Raman field. This technique was first used to observe NMR transitions in rare earth compounds^{29,41} and later also to ESR⁴² and ENDOR.^{43,44}

Figure 13 shows the Raman heterodyne signal, again from $\text{Pr}^{3+}:\text{YAlO}_3$, as a function of the frequency of the rf field. For this spectrum we applied a small magnetic field of a few gauss, so that the transitions between the $+\frac{1}{2}$ and $+\frac{3}{2}$ states were no longer degenerate with the transition from the $-\frac{1}{2}$ to the $-\frac{3}{2}$ state. In addition, the crystal has two nonequivalent sites, resulting in a total of four lines which are assigned in the figure. Again, the width of these resonance lines is independent of the laser linewidth and only due to the properties of the crystal.

In these experiments, the laser beam interacts directly with the atom whose nuclear spin transitions are the subject of interest. In other cases, spin-spin couplings exchange polarizations with neighboring spins. It is then possible to polarize optically those spins and detect their NMR transitions optically.^{45,46} In other cases, the interaction between two neighboring atoms manifests itself more strongly in the optical transition. The position of the optical resonance within the inhomogeneously broadened resonance line allowed the assignment of the magnetic resonance spectrum to a pair of neighboring spins.⁴⁷ While most experiments of this type were performed in ionic materials, color centers in diamond have also been studied.⁴³

3.2 Semiconductors

Semiconductors have become a very active area for applications of optically enhanced magnetic resonance. The

Figure 14 Optical pumping in semiconductors: level scheme for a III-V compound with tetrahedral symmetry

first demonstrations of the technique were performed in GaAs.⁴⁸ For the optical excitation, one usually chooses a photon energy at the exciton resonance or just above the band gap, thereby creating holes at the top of the valence band and electrons at the bottom of the conduction band. Under these conditions, the system behaves to some degree like free atoms. Figure 14 shows the relevant band structure for the technically important case of a III-V semiconductor with tetrahedral symmetry.

In these compounds, the valence band consists of p type orbitals ($L = 1$). Spin-orbit coupling splits the band into a $J = \frac{1}{2}$ and a $J = \frac{3}{2}$ subband. The conduction band consists of s type orbitals and the total electronic angular momentum of the excited electrons is therefore $J = \frac{1}{2}$. Absorption of a circularly polarized photon by an electron in the $J = \frac{1}{2}$ valence band then creates a hole and a conduction band electron, both with $J_z = +\frac{1}{2}$. In the valence band as well as in the conduction band the electron spin system becomes polarized to some degree that depends on the thermalization times of the hole and the electron. As in the case of free atoms, the spin polarization reflects itself in the polarization of the luminescence.

The hyperfine interaction between electrons and nuclear spins can transfer spin polarization from the electrons to nuclei. If resonant rf irradiation perturbs the nuclear spin reservoir, it also affects the electron spin polarization and the polarization of the luminescence. By observing the luminescence and scanning the radiofrequency in a constant magnetic field, it is thus possible to record magnetic resonance spectra.^{48,49} Figure 15 shows an example of such a spectrum from GaAs, reproduced from Krapf et al.⁴⁹ Two different isotopes of Ga are clearly visible, as well as the As resonance. The positions of the resonance lines depend on the polarization of the electron spins, as shown in the lower left part of the spectrum. Such experiments may well become an interesting addition to the analytical tools of the semiconductor industry. Most experiments performed up to now have used GaAs, but Si, Ge,⁵⁰ and InSb⁵¹ have also been investigated.

Apart from the polarization and intensity of the light, NMR transitions can also be observed indirectly through changes in the ESR resonance position:⁵² the coupling between the electronic and nuclear spins shifts the ESR transition frequency. By applying pulsed or CW radiofrequency fields to the nuclear spins, it is possible to change their polarization and thereby the ESR frequency. If the number of spins is large enough, it is even possible to observe the NMR spectrum directly in a conventional spectrometer modified for optical pumping.⁵³

Figure 15 Example of optically detected NMR spectrum of GaAs. The signal was recorded by scanning the radiofrequency and observing the luminescence in a constant magnetic field of 0.17 T

The high sensitivity of optical techniques is a very attractive feature for studying the thin films used in integrated circuits. The optical techniques could become even more attractive for studying quantum confined structures.⁵⁴ Confinement of the conduction electrons to small regions, like quantum wells, quantum wires, or quantum dots, modifies the optical absorption spectra considerably. It is then possible to selectively excite only those areas where the electrons are confined and to measure magnetic resonance spectra specifically from those areas. Such experiments therefore require not only high sensitivity for measuring signals from small parts of the sample, but also good selectivity to extract this signal from the large background of the entire sample.

3.3 Surfaces

Quasi two-dimensional systems have always proved difficult to investigate by conventional NMR, since the number of spins in these systems is quite small.^{55,56} Increasing the spin polarization by optical pumping has significantly improved the sensitivity of this type of experiment. In particular, the transfer of spin polarization from optically pumped alkali atoms to Xe nuclear spins¹⁵ has allowed the study of the effect of surfaces on the magnetic resonance spectrum.^{57,58} In the fast exchange regime, the distribution of spins between the surface adsorbate and vapor phase determines the averaged magnetic resonance spectrum. For oriented surfaces, where most spins are in the vapor phase, the splittings and shifts are then in the mHz range, requiring highly sensitive detection methods. Other work has therefore concentrated on systems with a large surface-to-volume ratio like zeolites⁵⁹ where most of the atoms are close to the interface.

For experiments with oriented surfaces, apart from the sensitivity advantages, the use of light for optical pumping as well as for detection also brings the possibility of selecting signal contributions that originate from atoms which are close to the surface. For this purpose, changes in the penetration depth of light with wavelength⁶⁰ have been used, but more frequently the selection is achieved by reflecting a laser beam from the interface being investigated. The reflection coefficient for the laser beam depends on the refractive indexes on both

Figure 16 Principle of optical detection of magnetic resonance close to a surface. The refractive indices on both sides of the interface are denoted as n_1 and n_2

sides of the interface and is therefore affected by atoms close to the interface that are resonant with the laser light (see Figure 16). The changes in the reflection coefficient, which can be measured through changes of the amplitude and polarization of the reflected beam, therefore contain information on the atoms close to the interface. The combination of optical pumping with this type of optical detection provides sufficient sensitivity such that it is no longer necessary to use samples with high surface-to-volume ratios and permits the study of oriented surfaces.

One method that relies on such a technique allowed the study of the nuclear quadrupole resonances of Pr^{3+} in LaF_3 .⁶¹ In this case, the beam was reflected from an optically dense material. The reverse is also possible: if the laser beam undergoes total internal reflection at an interface to an optically less dense medium, an evanescent wave penetrates into the thinner medium by a distance of the order of the optical wavelength. Atoms in this evanescent wave can thus modify the reflected laser beam by absorbing light from it and by their effect on the reflection coefficient.⁶²

3.4 Molecules

Conventional magnetic resonance has been applied most successfully to molecular systems. These systems can also be investigated with optical methods. Aromatic organic molecules are particularly suitable because their chromophores make optical spectroscopy particularly attractive. Experiments with these systems typically use optical excitation from the ground state to an excited singlet state with a pulsed UV laser. From the excited singlet state, intersystem crossing (ISC) can populate a nearby triplet state (see Figure 17). The intersystem crossing populates the different levels of the triplet state unequally. In addition, the triplet substates have in general different lifetimes. The polarization and intensity of the

Figure 17 Principle of optically detected magnetic resonance in excited triplet states

phosphorescence depend on the population of the individual states and allow an assessment of the population differences. By applying rf fields to the system, it is possible to induce transitions between the different triplet states; these transitions can be observed in the phosphorescence. Similar experiments have been performed on many other systems. Two groups demonstrated the high sensitivity of the method very strikingly by measuring the magnetic resonance of individual pentacene molecules in *p*-terphenyl hosts.^{1,2} Work is now in progress to extend these experiments to NMR transitions.

1 INTRODUCTION

Transfer of spin order is of great importance in magnetic resonance and plays a crucial role in two-dimensional correlation spectroscopy, two-dimensional exchange spectroscopy, and for the sensitivity enhancement of low- γ nuclei. Well-known examples are Hartmann–Hahn cross polarization,^{1,2} spin diffusion,³ INEPT,⁴ and NOESY⁵ experiments.

All experiments mentioned above are ‘sudden’ experiments in the sense that they start with the preparation of an initial state characterized by a density operator which corresponds to a non-equilibrium state. Such a non-equilibrium state evolves under the transfer Hamiltonian. The time-evolution of the density operator leads to a transfer of spin order. In an adiabatic experiment, on the other hand, one starts with a density operator that does not evolve under the initial Hamiltonian. The time evolution is initiated by ‘slowly’ and continuously changing the Hamiltonian in the course of the spin-order transfer such that the density operator follows the Hamiltonian.

A simple example to illustrate the differences between sudden and adiabatic experiments is the inversion of the z -magnetization of a single spin 1/2. The ‘sudden’ version is a π -pulse applied on-resonance with a pulse duration of $\tau = \pi/\omega_1$. The behavior of the magnetization during the pulse is illustrated in Figure 1(a,c). Critical settings for obtaining perfect inversion are the resonance frequency (which must be ‘on-resonance’, i.e., $\omega_{\text{rf}} \approx \omega_0$) and the product of pulse length τ and rf-field strength ω_1 . The well-known oscillatory behavior of M_z as a function of the pulse length (Figure 1c) is typical for ‘sudden’ experiments. The adiabatic counterpart of such an inversion pulse is an adiabatic passage through resonance realized by a frequency sweep of the rf-irradiation frequency $\omega_{\text{rf}}(t)$. The behavior is illustrated in Figure 1(b,d). The inversion starts by irradiating the spin system with an

irradiation frequency $\omega_{\text{rf}}(0)$ much lower than the resonance frequency ω_0 and ends with a frequency $\omega_{\text{rf}}(\tau)$ much higher than ω_0 . The precise shape of the frequency sweep $\omega_{\text{rf}}(t)$ is only important if one is interested in minimizing the pulse length at a certain ‘degree of adiabaticity’. The Hamiltonian in the rotating frame (rotating with frequency ω_0 about the static magnetic field) is given by

$$\mathcal{H} = \chi(t)I_z + \omega_1 I_x \quad (1)$$

where $\chi(t) = \omega_{\text{rf}}(t) - \omega_0$ is the off-resonance term. As a function of the time t , the Hamiltonian is rotated from being parallel with I_z to being antiparallel with I_z . As long as the frequency sweep $\omega_{\text{rf}}(t)$ is slow enough (see below) and the sweep range is large enough ($|\omega_{\text{rf}}(0) - \omega_0| \gg |\omega_1|$ and $|\omega_{\text{rf}}(\tau) - \omega_0| \gg |\omega_1|$), the magnetization is inverted irrespective of the exact values of the resonance frequency ω_0 , the sweep length τ , and the rf-field strength ω_1 . It will become clear in the following, that the polarization transfer experiments of interest are also fully described, for two spin systems, by the simple picture of Figure 1. The polarization transfer will take place in a fictitious spin-1/2 subspace. The only difference to the inversion of z -magnetization will be the labelling of the axes.

In the absence of relaxation, the time evolution of a spin system always conserves the entropy and the total spin order. It is, therefore, in principle reversible and ‘adiabatic’ in a thermodynamical sense. This is obvious for the simple example of Figure 1 but has also been shown for polarization transfer processes in multi-spin systems for the case of spin diffusion^{6,7} and cross polarization.^{8,9} In the present context, we use the term adiabatic in a more restricted sense, namely for processes where in addition to the conservation of spin order, the density operator and the instantaneous Hamiltonian commute at all times,¹⁰ i.e.,

$$[\sigma(t), \mathcal{H}(t)] = 0 \quad (2)$$

In this chapter, we will treat the transfer of polarization or longitudinal magnetization between two spins. We start with z -magnetization on a source spin (spin 1) as described by a density operator of the form $\sigma(0) = cI_{1z}$ and measure the amount of polarization on the destination spin (spin 2) after the transfer. The final density operator is of the form $\sigma(\tau) = c'(\tau)I_{2z} + Z(\tau)$ and we can abbreviate the transfer as $I_{1z} \rightarrow I_{2z}$. Here $Z(\tau)$ describes the part of the density operator orthogonal to I_{2z} . We define the polarization P_k of spin k as the expectation value of the operator I_{kz} . The polarization is related to the longitudinal magnetization by $M_{kz} = N_k \hbar \gamma_k P_k$. In general, neither the magnetization nor the polarization of the entire spin system are conserved quantities,¹¹ but there is an important class of experiments where the sum polarization $\sum_k P_k$ is conserved. Therefore, we will discuss the experiments always in terms of polarization.

Polarization transfer is a special form of the more general term spin-order transfer. Other examples of spin-order transfer include coherence transfer, e.g., $I_{1x} \rightarrow I_{2x}$, and transfer of coherences to two-spin order terms, e.g., $I_{1x} \rightarrow 2I_{1y}I_{2z}$. The distinction between polarization and coherence depends on the frame of reference and is not always unique.

Figure 1 Schematic comparison of (a) sudden and (b) adiabatic inversion of the z -component of the magnetization vector. In the sudden case a π pulse is applied while in the adiabatic case a frequency sweep is shown. The time evolution of the z -magnetization as a function of the pulse duration τ is shown in (c) and (d) for sudden and adiabatic schemes, respectively. For the sudden experiment, the precise choice of τ is crucial to obtain efficient inversion; for adiabatic experiments a variation within rather wide limits does not lead to significant changes in inversion efficiency

Polarization transfer between two spins can often be described by a fictitious spin-1/2 system.^{12,13} This is a consequence of the structure of the dipolar-coupling interaction, which has a matrix representation in the product base $|\alpha\alpha\rangle, |\alpha\beta\rangle, |\beta\alpha\rangle, |\beta\beta\rangle$ of the form

$$\frac{1}{2} \begin{bmatrix} \xi^\Sigma & 0 & 0 & d^\Sigma \\ 0 & \xi^\Delta & d^\Delta & 0 \\ 0 & d^\Delta & \xi^\Delta & 0 \\ d^\Sigma & 0 & 0 & \xi^\Sigma \end{bmatrix} \quad (3)$$

There are no coupling elements between the sum-polarization subspace spanned by $|\alpha\alpha\rangle, |\beta\beta\rangle$ and the difference polarization subspace spanned by $|\alpha\beta\rangle, |\beta\alpha\rangle$. The scalar J -coupling Hamiltonian has the same basic structure. If, besides the dipolar interaction, only a 'Zeeman-type' interaction of the form

$$\frac{1}{2} \begin{bmatrix} \chi^\Sigma & 0 & 0 & 0 \\ 0 & \chi^\Delta & 0 & 0 \\ 0 & 0 & -\chi^\Delta & 0 \\ 0 & 0 & 0 & -\chi^\Sigma \end{bmatrix} \quad (4)$$

is present, the total Hamiltonian can be written as the sum of two fictitious spin-1/2 Hamiltonians

$$\mathcal{H} = \mathcal{H}^\Sigma \oplus \mathcal{H}^\Delta \quad (5)$$

with

$$\mathcal{H}^\kappa = \chi^\kappa \cdot S_z^\kappa + d^\kappa \cdot S_x^\kappa + \frac{1}{2} \xi^\kappa \cdot 1I^\kappa \quad (6)$$

where κ stands for either Σ (the double-quantum subspace) or Δ (the zero-quantum subspace) and $1I^\kappa$ is the identity operator in the considered subspace. The symbol ' $\oplus$ ' emphasizes that we take the direct sum of the two subspaces of dimension 2×2 . Not considering the term proportional to the identity operator which does not influence the evolution of the density operator in the subspace κ , the Hamiltonian

$$\mathcal{H}^\kappa = \chi^\kappa \cdot S_z^\kappa + d^\kappa \cdot S_x^\kappa \quad (7)$$

has the same form as the one of equation (1) with the dipolar amplitude coupling element d^κ taking the role of the rf field in equation (1). The separation into a sum and difference subspace can also be applied to the density operator σ , given that $\sigma(0)$ can be divided according to

$$\sigma = \sigma^\Sigma \oplus \sigma^\Delta \quad (8)$$

If the density operator contains only terms proportional to I_z , such a separation is always possible according to

$$\sigma = p_1 I_{1z} + p_2 I_{2z} = p^\Sigma I_z^\Sigma + p^\Delta I_z^\Delta \quad (9)$$

with $p^\Sigma = p_1 + p_2$, $p^\Delta = p_1 - p_2$, $I_z^\Sigma = 1/2(I_{1z} + I_{2z})$, and $I_z^\Delta = 1/2(I_{1z} - I_{2z})$. Obviously, the inversion of the difference polarization $I_z^\Delta \rightarrow -I_z^\Delta$ is equivalent to a complete polarization transfer, i.e., $I_{1z} \rightarrow I_{2z}$ while the inversion of the sum magnetization $I_z^\Sigma \rightarrow -I_z^\Sigma$ leads to the polarization transfer $I_{1z} \rightarrow -I_{2z}$.

In polarization transfer schemes based on the dipolar coupling, the value of the effective dipolar coupling constant d^k depends on one or two of the three Euler angles which describe the orientation of the crystallite in the rotor-fixed frame. For a powder sample, the resulting distribution of effective dipolar coupling frequencies does not allow a complete polarization inversion by the equivalent of a 180° pulse with $\tau \cdot d^k = \pi$. An optimum choice of the pulse length τ leads to a maximum transfer efficiency for such a ‘sudden’ experiment of 73% and to an equilibrium value of 50% in an isolated two-spin system. For adiabatic methods, the maximum transfer efficiency is still 100% even in a powder sample. It will be shown below, that adiabatic polarization transfer schemes show a greatly reduced sensitivity to rf-field inhomogeneities compared to their sudden equivalent.

If the adiabaticity is violated during the sweep, the density operator and the Hamiltonian do not commute at all times during the polarization-transfer process ($[\mathcal{H}(t), \sigma(t)] \neq 0$). Under this condition, the density operator starts to precess around the Hamiltonian. Such a precession will be damped by relaxation and possibly rf-field inhomogeneities and lead to a reduction in transfer efficiency.

A number of adiabatic heteronuclear polarization transfer methods have been introduced starting with the ADRF-ARRF scheme for static samples^{2,14,15} and the static adiabatic passage through the Hartmann–Hahn matching condition.¹⁶ Adiabatic passage Hartmann–Hahn cross polarization (APHH CP) can also be applied under MAS.^{17–21} In these experiments, the amplitude difference of the two applied rf-fields $\omega_{1I}(t) - \omega_{1S}(t)$ is the parameter $\chi(t)$ which is varied in an adiabatic fashion around the Hartmann–Hahn matching condition, i.e., $\chi(t) = \omega_{1I}(t) - \omega_{1S}(t) - f \cdot \omega_r$ with $f = \pm 1, \pm 2$. The variation can also take place around the original Hartmann–Hahn condition with $f = 0$ if the adiabatic transfer is combined with multiple-pulse irradiation.²²

There is also a number of homonuclear adiabatic polarization transfer schemes under MAS. In adiabatic passage rotational resonance (APRR)²³ the spinning frequency of the MAS rotor $\omega_r(t)$ is varied to obtain a sweep through the rotational resonance condition^{24–26} $\Omega_1 - \Omega_2 = n\omega_r$ with $n = \pm 1, \pm 2$ and Ω_k being the isotropic chemical shift of spin k . This leads to the definition $\chi(t) = \Omega_1 - \Omega_2 - n\omega_r(t)$. Adiabatic passage RR was also applied to the central transition of half-integer quadrupolar spins where conventional RR cannot be applied due to the broadening of the resonances by second-order quadrupolar terms.²⁷ A variation of APRR is the rotational resonance tickling experiment^{28–30} where the RR experiment is carried out in a tilted rotating frame and the sweep is accomplished at constant MAS frequency by changing the amplitude of the applied rf-field.

In the adiabatic version of the homonuclear rotary-resonance (HORROR) experiment³¹ called dipolar recoupling enhancement through amplitude modulation (DREAM)^{32,33} the amplitude of the applied rf-field $\omega_1(t)$ is varied as a function of time to obtain an adiabatic sweep through the HORROR recoupling condition $n \cdot \omega_1 = \omega_r$ with $n = \pm 1, \pm 2$ leading

to $\chi(t) = \omega_r - n \cdot \omega_1(t)$. Recently a rf-field-driven dipolar recoupling scheme for half-integer quadrupolar nuclei was introduced³⁴ which can also be implemented in an adiabatic fashion.

2 THEORY

A spin system which is subject to magic-angle sample spinning (MAS) and to a slow variation of a parameter due to an adiabatic process can be described by a time-dependent Hamiltonian $\mathcal{H}(t, T)$. In this notation, the time-variable t characterizes the fast time dependence due to the MAS and the time-variable T describes the slow time dependence due to the adiabatic variation of a spin-system variable. If we assume that the changes due to T can be neglected over a time period $\tau_r = 2\pi/\omega_r$ then we can define a t -time averaged Hamiltonian

$$\mathcal{H}(T) = \langle \mathcal{H}(t) \rangle_{\tau_r} \quad (10)$$

which no longer depends on the time-variable t and is, therefore, independent of the MAS rotation. There are several ways of carrying out the averaging. The most common descriptions use average Hamiltonian and Floquet theory. The details of this averaging process depend on the specific polarization transfer process under discussion. Different approaches have been used and can be found in the original literature (see below).

For a pair of spins $1/2$, the relevant process of the adiabatic polarization transfer can always be described in a subspace κ of the Hamiltonian which is defined by a fictitious spin- $1/2$ system.^{12,13} The T -time dependent system Hamiltonian in this subspace is given by

$$\mathcal{H}^\kappa(T) = \chi^\kappa(T) \cdot S_z^\kappa + |d_{\text{eff}}^\kappa| \cdot (\cos(\varphi)S_x^\kappa + \sin(\varphi)S_y^\kappa) \quad (11)$$

Equation (11) is a trivial generalization of equation (7) caused by the fact that the effective dipolar coupling d_{eff}^κ appearing in the context of recoupling experiments is a complex number with absolute value $|d_{\text{eff}}^\kappa|$ and the phase $\arg(d_{\text{eff}}^\kappa) = \varphi$. The size of $|d_{\text{eff}}^\kappa|$ depends on the two Euler angles α and β which describe the rotation from the principal-axis system of the dipolar interaction tensor to the rotor-fixed coordinate system. The third Euler angle γ determines the phase φ but does not influence the magnitude of the coupling, $|d_{\text{eff}}^\kappa|$. The phase is simply an integer multiple of γ where the integer depends on the matching condition employed. In a powder sample each crystallite has a different Euler angle γ and, therefore, a different phase φ . The Hamiltonian for each crystallite lies in a different plane spanned by the operators S_z^κ and $\cos(\varphi)S_x^\kappa + \sin(\varphi)S_y^\kappa$. To simplify the theoretical description we can rotate the Hamiltonian by the crystallite-dependent angle φ about $-S_z^\kappa$ and recover the simple form of equation (7):

$$\mathcal{H}^\kappa(T) = \chi^\kappa(T) \cdot S_z^\kappa + |d_{\text{eff}}^\kappa| \cdot S_x^\kappa \quad (12)$$

In the course of the adiabatic polarization transfer the effective chemical-shift term is changed from $\chi(0) = \chi_i$ to $\chi(\tau) = \chi_f$ (where χ_i and χ_f have a different sign) in such a way that the adiabaticity condition

$$a(T) = \frac{\sqrt{\chi^\kappa(T)^2 + |d_{\text{eff}}^\kappa|^2}}{|d\Theta^\kappa(T)/dT|} \gg 1 \quad (13)$$

is fulfilled for all times T . Note that the adiabaticity parameter is T -time dependent. Here, the angle $\Theta^\kappa(T) = \arctan(|d_{\text{eff}}^\kappa|/\chi^\kappa(T))$ describes the time-dependent angle between the Hamiltonian and the z -axis. We start at time $T = 0$ with an initial density operator $\sigma^\kappa(0^-) = p^\kappa \cdot S_z^\kappa \approx c \cdot \mathcal{H}^\kappa(0)$ along the z -axis of the subspace κ . If the Hamiltonian $\mathcal{H}^\kappa(0)$ is not parallel with the z -axis, e.g., if the initial offset is not large enough, only the part of the initial density operator that is parallel to the Hamiltonian $\mathcal{H}^\kappa(0)$ has to be taken into account for the further course of the experiment. We denote the density operator just before a projection step at time t by $\sigma^\kappa(t^-)$ and just after the projection step by $\sigma^\kappa(t^+)$. Each projection decreases the spin order because the orthogonal components are assumed to decay irreversibly. After the projection we obtain

$$\sigma^\kappa(0^+) = p^\kappa \cdot \cos(\Theta(0)) S_{\text{eff}}^\kappa(0) \quad (14)$$

where the cosine of the angle $\Theta(0) = \arctan(|d_{\text{eff}}^\kappa|/\chi_i^\kappa)$ determines the initial loss of polarization due to the projection on the operator $S_{\text{eff}}^\kappa(0)$. This projection is schematically illustrated in Figure 2. The operator

$$S_{\text{eff}}^\kappa(T) = \cos(\Theta(T)) S_z^\kappa + \sin(\Theta(T)) S_x^\kappa \quad (15)$$

stays always parallel to the Hamiltonian. Ideally, the sweep is applied such that $\Theta(0) \approx 0$ and

$$\sigma^\kappa(0^+) \approx p^\kappa \cdot S_z^\kappa \quad (16)$$

If the effective coupling $|d_{\text{eff}}^\kappa|$ is non-zero and equation (13) is fulfilled, the density operator always stays parallel to the Hamiltonian (i.e., along $S_{\text{eff}}^\kappa(T)$) and follows the movement of the Hamiltonian and describes an arc in the plane spanned by S_z^κ and $\cos(\varphi) S_z^\kappa + \sin(\varphi) S_y^\kappa$. For $\varphi = 0$, one obtains the following expression for the density operator during the adiabatic sweep:

$$\sigma^\kappa(T) = p^\kappa \cdot \cos(\Theta_i) S_{\text{eff}}^\kappa(T) \quad (17)$$

Figure 2 shows the trajectory followed by the density operator for a single arbitrary crystallite in the plane spanned by S_z^κ and $\cos(\varphi) S_z^\kappa + \sin(\varphi) S_y^\kappa$ as a function of the time-variable T . For a powder each crystallite follows such a trajectory but due

Figure 2 Schematic representation of the adiabatic polarization transfer for a single crystallite orientation in the subspace spanned by S_z^κ and S_x^κ . The initial projection with $\Theta(0)$ the subsequent rotation imposed by the rotation of the Hamiltonian, and the final projection with $\Theta(\tau)$ of the density operator is shown

to the variation in the phase φ for the different crystallites the planes are different. At time $T = 0$ the magnetization of all crystallites are aligned along S_z^κ . At the center of the sweep at $\chi^\kappa(T = \tau/2) = 0$ the magnetization is distributed over the plane spanned by S_x^κ and S_y^κ depending on the value of φ . At the end of the sweep at $T = \tau$ the magnetization of all different crystallites is again aligned but now along $-S_z^\kappa$.

The density operator at the end of the sweep at $\chi^\kappa(\tau) = \chi_f^\kappa$ is then given by

$$\sigma^\kappa(\tau^-) = p^\kappa \cdot \cos(\Theta(0)) \cdot [\cos(\Theta(\tau)) S_z^\kappa + \sin(\Theta(\tau)) S_x^\kappa] \quad (18)$$

where the angle $\Theta(\tau) = \pi + \arctan(|d_{\text{eff}}^\kappa|/\chi_f^\kappa)$. We have to project the density operator at the end of the sweep onto the z -axis of the subspace κ and obtain the final density operator

$$\sigma^\kappa(\tau^+) = p^\kappa \cdot \cos(\Theta(0)) \cos(\Theta(\tau)) S_z^\kappa \quad (19)$$

For a well-designed experiment, we require that $\Theta(0) \approx 0$ and $\Theta(\tau) \approx \pi$ leading to

$$\sigma^\kappa(\tau^+) \approx -p^\kappa \cdot S_z^\kappa \quad (20)$$

The loss of polarization caused by the two projections at the beginning and the end of the sweep are expressed by the factors $\cos(\Theta(0))$ and $\cos(\Theta(\tau))$ in equation (19), respectively, and can be minimized by starting and ending the adiabatic sweep with initial and final values of the effective chemical shift largely exceeding the value of the effective coupling frequency $|d_{\text{eff}}^\kappa|$.

If the effective coupling $|d_{\text{eff}}^\kappa|$ is zero, the density operator is unchanged by the sweep and we obtain a final density operator $\sigma^\kappa(\tau) \approx \sigma^\kappa(0) = p^\kappa \cdot S_z^\kappa$, assuming that $\Theta(0) \approx 0$ and $\Theta(\tau) \approx \pi$.

In principle, any continuous shape for $\chi^\kappa(T)$ can be used which fulfills equation (13), but to minimize relaxation effects it is advantageous to use a sweep which is as short as possible while still maintaining adiabaticity at all times T . The best shape with respect to adiabaticity is a shape where the angular velocity $\alpha(T) = d\Theta(T)/dT$ is proportional to the effective field $\omega_{\text{eff}}(T) = \sqrt{|d_{\text{eff}}^\kappa|^2 + \chi^\kappa(T)^2}$. This requirement is fulfilled for a sweep rate of^{35,36}

$$\frac{d}{dT} \chi^\kappa(T) \propto \frac{(|d_{\text{eff}}^\kappa|^2 + \chi^\kappa(T)^2)^{3/2}}{|d_{\text{eff}}^\kappa|} \quad (21)$$

Such a function leads to a fast change of $\chi^\kappa(T)$ far from the center of the sweep and a slow change close to the center. To design such a sweep, the sweep has to fulfill the condition $\chi^\kappa(\tau/2) = 0$ which is not possible for all spins in the presence of chemical-shift offsets or rf-field inhomogeneity. A linear sweep of

$$\chi^\kappa(T) = \chi_i^\kappa - \left(\frac{\chi_i^\kappa - \chi_f^\kappa}{\tau} \cdot T \right) \quad (22)$$

is the shape which shows the smallest sensitivity to the value of the system parameters but requires the longest sweep time to remain adiabatic during the entire sweep. In practice, a good compromise is to maintain constant angular velocity during the

sweep for a ‘typical’ value of the dipolar coupling constant d_{est} which can be implemented by the function

$$\alpha(T) = \frac{d\Theta(T)}{dT} = \frac{2}{\tau} \cdot \arctan\left(\frac{\chi_i}{|d_{\text{est}}|}\right) \quad (23)$$

Such a solution leads to the functional form

$$\chi^\kappa(T) = |d_{\text{est}}| \cdot \tan\left(\alpha \cdot \left[\frac{\tau}{2} - T\right]\right) \quad (24)$$

for $0 \leq T \leq \tau$ which is more tolerant than the one described by equation (21) to an imprecise estimation of the parameters for the center of the sweep and to the variation of $d_{\text{eff}}(\alpha, \beta, \gamma)$ as a function of the crystallite orientation.

In principle, one can achieve 100% polarization transfer using adiabatic methods compared to a maximum of 73% efficiency using ‘sudden’ methods. This requires of course, that the polarization transfer process is in the adiabatic limit ($a(T) \gg 1$) for all orientation-dependent effective coupling frequencies $d_{\text{eff}}(\alpha, \beta, \gamma)$. This increased efficiency is due to the fact that the transfer speed of the adiabatic polarization transfer is independent of the Euler angles and of the orientation-dependent size of the effective coupling constant. As was shown earlier, the Euler angle γ only influences the phase in the $S_x^\kappa - S_y^\kappa$ -plane where the trajectory crosses but all trajectories reach the final point at the same point in time (Figure 2b).

3 METHODS OF HETERONUCLEAR POLARIZATION TRANSFER

3.1 Hartmann–Hahn Cross Polarization by Adiabatic Passage

Adiabatic Passage Hartmann–Hahn cross polarization (APHH)^{16–21} was designed to combine the advantages of Hartmann–Hahn cross polarization, namely the conservation of the sum polarization, with the advantages of ADRF-ARFF which has a higher transfer efficiency and no critical matching condition. In this experiment the amplitude of one or both of the rf-fields is changed in an adiabatic fashion during the cross-polarization time period (Figure 3) in order to obtain a sweep through the sideband f of the Hartmann–Hahn matching condition $\omega_{1I} - \omega_{1S} = f \cdot \omega_r$.

In the APHH experiment, the sum polarization and σ^Σ are constants of the motion and the relevant subspace of the heteronuclear two-spin Hamiltonian is the zero-quantum subspace $\kappa = \Delta$. The Hamiltonian in this subspace has exactly the form of equation (7)

$$\mathcal{H}^\Delta(T) = \chi^\Delta(T) \cdot S_z^\Delta + |d_{f,\text{eff}}| \cdot S_x^\Delta \quad (25)$$

with $\chi^\Delta(T) = \omega_{1I}(T) - \omega_{1S}(T) - f\omega_r$ where $\omega_{1I}(T)$ and $\omega_{1S}(T)$ are the time-dependent amplitudes of the applied rf fields. The parameter $f = \pm 1, \pm 2$ denotes the sideband of the Hartmann–Hahn matching condition under MAS^{37–39} and $d_{f,\text{eff}}$ is the Fourier coefficient of order f of the heteronuclear dipolar coupling. In APHH CP the initial and final value of the amplitude sweep $\chi_i^\Delta = \omega_{1I}(0) - \omega_{1S}(0) - f\omega_r$ and $\chi_f^\Delta = \omega_{1I}(\tau) - \omega_{1S}(\tau) - f\omega_r$ are limited to about $\pm 1/2\omega_r$.

Figure 3 Pulse sequence used for adiabatic cross polarization. The amplitude modulation during the cross-polarization time can be applied either to the proton (a) or to the carbon (b) channel. Cross polarization uses of phase X

in order not to touch one of the other sideband matching conditions. The fictitious spin-1/2 operators in the zero-quantum subspace are defined as $S_z^\Delta = 1/2 \cdot (I_z - S_z)$, $S_x^\Delta = 1/2 \cdot (S^+ I^- + S^- I^+)$, and $S_y^\Delta = i/2 \cdot (S^+ I^- - S^- I^+)$, where the z -axis (defining I_z and S_z) is chosen along the effective field direction in the rotating frame.⁴⁰ Rotating the density operator in the zero-quantum subspace from S_z^Δ to $-S_z^\Delta$ leads to a complete transfer of magnetization from I_z to S_z because the double-quantum subspace density operator does not evolve during the APHH period of the experiment.

The above description assumes the ideal case of an isolated dipolar-coupled two-spin system where both spins are on-resonance. In the presence of chemical-shift offsets the amplitudes of the rf-fields have to be replaced by the effective fields $\omega_{I,\text{eff}} = \sqrt{(\omega_{1I}(T))^2 + \Omega_I^2}$ and $\omega_{S,\text{eff}} = \sqrt{(\omega_{1S}(T))^2 + \Omega_S^2}$, respectively.⁴⁰ In addition, the effective dipolar-coupling frequency $d_{f,\text{eff}}$ becomes weakly time dependent with T .

Adiabatic cross polarization can also be done using the J coupling as a transfer mechanism in liquid^{41,42} and solid⁴³ samples. If we consider the isotropic J -coupling in addition to the dipolar coupling, we can get polarization transfer under MAS for the $f = 0$ matching condition⁴³ with $d_{0,\text{eff}} = J$. If the system is not isolated but has homonuclear dipolar couplings we can also get polarization transfer for the $f = 0$ and for the $|f| > 2$ matching conditions and the coupling strength of the $f = \pm 1, \pm 2$ matching conditions is modified.

The experimental results of Figure 4 show that adiabatic-passage Hartmann–Hahn cross polarization yields an S-spin signal that is always equal to or larger than the one obtained using Hartmann–Hahn cross polarization with the same contact time. At longer contact times where the transient oscillations⁴⁴ are dying out (in the example of Figure 4 for $\tau > 0.4$ ms) a gain of a factor of two in signal is

Figure 4 Comparison of the cross-polarized magnetization in Hartmann-Hahn cross polarization (solid line) and adiabatic passage Hartmann-Hahn cross polarization (open circles) measured on a sample of 10% $2\text{-}^{13}\text{C}\text{-}3,3,3\text{-}^2\text{H}$ -alanine diluted in perdeuterated alanine. The Hartmann-Hahn cross polarization shows the transient oscillations of the one-bond heteronuclear carbon-proton dipolar coupling as a function of the cross-polarization time τ . The adiabatic passage cross polarization is also shown as a function of the total sweep length and leads to a signal which is larger by a factor of almost two. The experiments were carried out at a spinning speed of $\omega_r/2\pi = 22$ kHz using the $f - 1$ matching condition and a proton field strength of $\omega_{1H}/2\pi = 108$ kHz. (Figure courtesy of René Verel)

observed caused by an improved polarization transfer. The theoretical gain of the APHH CP compared to the conventional cross polarization experiment in larger spin systems (IS_n) have been investigated.²¹ It was found that APHH CP should always outperforms CP by a factor close to two. For a large system with $n \rightarrow \infty$, the theoretical gain is again two²¹ although experimentally much lower gains have been found.¹⁷

A further benefit of the APHH CP experiment is the insensitivity to the matching condition. For small dipolar couplings and fast spinning, the Hartmann-Hahn match is very narrow. It can become quite difficult to match the rf amplitudes and to keep the rf amplitude stable enough over the course of signal accumulation.⁴⁵ An example for such a difficult system is $^{13}\text{C}\text{-}^{15}\text{N}$ cross polarization. For the APHH experiments,²⁰ these difficulties are greatly reduced because the precise matching condition will be fulfilled at some time during the sweep. The exact position does not play a significant role. Figure 5 shows an example of a heteronuclear $^{13}\text{C}\text{-}^{15}\text{N}$ correlation experiment where APHH cross polarization between ^{13}C and ^{15}N was used to establish the chemical-shift correlation.²⁰

An additional gain in signal intensity can be realized due to the relative insensitivity of APHH cross polarization to rf-field inhomogeneities. Only part of the sample is exactly at the Hartmann-Hahn match of the rf-fields in normal cross polarization. This problem is overcome by APHH cross polarization where all spins go through the matching condition but at different times during the sweep. A similar approach can also be used in ‘sudden’ experiments by ramping the amplitude

Figure 5 Chemical shift correlation spectrum for a fully ^{13}C , ^{15}N -labelled sample of the cyclic decapeptide antamanide using adiabatic passage Hartmann-Hahn cross polarization. The resulting spectrum correlates each amide nitrogen N_κ with the directly attached carbons: C_α^κ in the same residue and $\text{C}_{\alpha-1}^\kappa$ in the previous residue. (Figure courtesy of Dr. Andreas Detken)

Figure 6 Multiple adiabatic sweeps through the Hartmann-Hahn matching condition allow the reversible transfer of magnetization between protons and carbons. The experiments were carried out using a sample of 10% $2\text{-}^{13}\text{C}\text{-}3,3,3\text{-}^2\text{H}$ -alanine diluted in perdeuterated alanine. The spinning speed was $\omega_r/(2\pi) = 22$ kHz. The $f = -1$ matching condition and a proton field strength of $\omega_{1H}/(2\pi) = 108$ kHz were used. Each of the four adiabatic sweeps had a length of 2 ms. For comparison we also show the intensity of the magnetization which was obtained in the corresponding Hartmann-Hahn cross-polarization experiment as a function of the cross-polarization time. (Figure courtesy of René Verel)

in a CP experiment.^{46,47} The ramp CP experiment leads to an equilibrium polarization of ca. 50% in two-spin systems even in the presence of rf-field inhomogeneity but the adiabatic gain of an additional factor of two can only be obtained if the design principles for an adiabatic transfer are employed.

The adiabatic gain can be experimentally verified by an experiment where several adiabatic sweeps are performed sequentially as shown in Figure 6. The behavior during the first sweep is completely equivalent to the one in Figure 5. During the second sweep ($2\text{ ms} \leq \tau \leq 4\text{ ms}$) the polarization is transferred back from the ^{13}C spins to the source spin(s), in this case the protons. The whole cycle can be repeated again without noticeable loss of polarization. The polarization in the adiabatic experiments flows back and forth approximately symmetrically around the equilibrium value obtained in a normal CP experiment. The initial jump in the magnetization at $\tau < 1\text{ ms}$ is due to the initial projection of equation (15).

4 METHODS OF HOMONUCLEAR POLARIZATION TRANSFER

4.1 Adiabatic Passage Rotational Resonance

In the adiabatic passage, rotational-resonance experiment (APRR)²³ the frequency of the rotor is changed during the course of the experiment such that the rotor frequency is swept through the rotational-resonance (RR) condition^{24–26} $\Omega_1 - \Omega_2 = n \cdot \omega_r$ in an adiabatic fashion (Figure 7). Such a spinning-frequency sweep can be achieved by suddenly increasing (decreasing) the air pressure on the drive air of the MAS rotor. This can be implemented either by changing

Figure 7 Pulse scheme of the APRR experiment. The pulse scheme follows the basic principle of two-dimensional exchange spectroscopy. The variation of the spinning rate was obtained by using a home-built setup consisting of a parallel arrangement of an air line with a needle valve to control the flow and an air line with a TTL-operated air-valve. This arrangement was placed in parallel with the spinning-speed controller. Upward and downwards spinning-speed ramps were produced by opening or closing the air valve using a user-defined TTL gate from the pulse programmer. Using a 4 mm rotor, a maximum slope of 6000 s^{-2} was obtained. For higher spinning speeds ($>5000\text{ Hz}$) downward ramps perform better, for low spinning speed upward ramps should be used. If a stable spinning frequency during the t_1 and t_2 periods is not required the linear ramp can be extended (dashed line) to include these time periods. (Figure adapted from Ref.²³)

Figure 8 (a) Two-dimensional ^{13}C chemical-shift correlation spectrum of uniformly ^{13}C labelled calcium-acetate monohydrate using RR as a mixing sequence. The strip from the 2D spectrum shows the carboxylic diagonal peaks and the cross peaks to the methyl group region for an experiment recorded at a constant spinning frequency matching the rotational resonance for the spin pair involving the most shielded carboxylic resonance. (b) Two-dimensional ^{13}C chemical-shift correlation spectrum of uniformly ^{13}C labelled calcium-acetate monohydrate using APRR as the mixing sequence. During the mixing time of 40 ms, the spinning frequency was ramped from 1.70 kHz to 1.88 kHz. The APHH passage covered all the $n = 4$ resonances between methyl and carboxylic spins. Four transients were co-added for each of the 256 t_1 increments recorded. The assignment of the resonance lines is given on top of the figure, the chemical shifts are referenced to TMS. Spinning sidebands are denoted by *. (Figure adapted from Ref.²³)

the setting of the spinning-speed controller from the pulse programmer or by using a magnetic valve which opens a bypass high-pressure line.

As the APHH CP experiment, the APRR experiment is a zero-quantum polarization-transfer experiment and the relevant Hamiltonian is the same as for APHH

$$\mathcal{H}^\Delta(T) = \chi^\Delta(T) \cdot S_z^\Delta + |d_{n,\text{eff}}| \cdot S_x^\Delta \quad (26)$$

except that $\chi^\Delta(T) = \Omega_1 - \Omega_2 - n\omega_r(T)$ where Ω_1 and Ω_2 are the isotropic chemical shifts of the two spins. The effective coupling $d_{n,\text{eff}}$ is given by the Fourier component $n = \pm 1, \pm 2$ of the homonuclear dipolar coupling. Again, a rotation of the density operator from S_z^Δ to $-S_z^\Delta$ induced by a variation of the MAS frequency, leads to a full transfer of magnetization from spin 1 to spin 2 as the double-quantum subspace is untouched.

In the presence of a non-vanishing chemical-shielding difference tensor the effective coupling frequencies are somewhat modified and higher-order matching conditions with $|n| > 2$ become allowed.

Figure 9 Pulse sequence for (a) the two-dimensional DREAM correlation experiment and (b) the DREAM spin-pair selective experiments. (c) Four different amplitude shapes which can be used in the spin-pair filter experiment and appropriate modification of the receiver phase. (Figure adapted from Ref.³³)

Figure 10 Cross polarization (a) and DREAM SPS (b) spectra of a mixture of $1\text{-}^{13}\text{C}_1$ -alanine, natural abundance methionine and natural abundance *iso*-leucine. The three substances were mixed in approximately equal weight parts and the sample restricted to the central region of the rotor with a total length of about 3 mm. A total of 3072 scans was co-added for each of the spectra. The spinning frequency was set to $\omega_r/2\pi = 28$ kHz and stabilized within 25 Hz with a spinning speed controller. (Figure adapted from Ref.³²)

One can perform the rotational-resonance experiment also in a tilted frame of reference where the chemical shifts of spins 1 and 2 have to be replaced by the effective fields $\omega_{1,\text{eff}} = \sqrt{(\omega_1(T))^2 + \Omega_1^2}$ and $\omega_{2,\text{eff}} = \sqrt{(\omega_2(T))^2 + \Omega_2^2}$, respectively.^{28–30} Instead of a sweep of the spinning frequency ω_r one can change the effective fields as a function of T . The experiment is almost completely equivalent to the spinning-frequency ramp except that the variation of $\chi^\Delta(T)$ is now caused by rf-field amplitude changes in full analogy to the APHH experiment.

Figure 8 shows a comparison of a standard RR experiment (Figure 8a) and an APRR experiment (Figure 8b) on a sample of uniformly labelled calcium acetate. The three different resonance lines in the carboxyl region of the spectrum are due to packing effects. The four crystallographically non-equivalent carbonyl carbons give rise to three resolved resonances. The APRR experiment is more broadband and covers all three resolved $^{13}\text{CH}_3\text{--}^{13}\text{COO}$ spin pairs while the RR experiment (Figure 8a) leads to transfer for one of these pairs only. Furthermore, APRR shows much higher cross peak intensity. For a fully adiabatic transfer we would expect all intensity to

be in the cross peaks with no intensity left in the diagonal peaks.

Rotational-resonance experiments on the central transition of a pair of dipolar-coupled half-integer quadrupolar spins can be described in full analogy to the rotational resonance experiments in spin-1/2 nuclei if at least one of the two quadrupolar nuclei has a large quadrupolar coupling constant. In half-integer quadrupolar nuclei the central transition is broadened by the second-order quadrupolar shift. Therefore, the conventional rotational-resonance experiment will only allow polarization transfer for a small number of spins which have an averaged chemical-shift difference close to the selected MAS rotation frequency. If we use a sweep through the rotational-resonance condition of all crystallites, then we are able to achieve recoupling for the whole second-order broadened powder pattern and we obtain polarization transfer independent of the crystallite orientation.²⁷

4.2 DREAM

In the DREAM experiment^{32,33} (Figure 9) a sweep of the rf-field amplitude through the HORROR recoupling condition³¹ $2 \cdot \omega_1 = \omega_r$ is used to transfer polarization between homonuclear dipolar-coupled spin pairs. The relevant subspace of the homonuclear dipolar-coupling Hamiltonian is the double-quantum subspace $\kappa = \Sigma$. The Hamiltonian in this subspace is again of the ‘standard form’ and is given by

$$\mathcal{H}^\Sigma(T) = \chi^\Sigma(T) S_z^\Sigma + |d_{1,\text{eff}}| S_x^\Sigma \quad (27)$$

with $\chi^\Sigma(T) = 2 \cdot \omega_1(T) - \omega_r$ where $\omega_1(T)$ is the time-dependent rf-field amplitude and $d_{1,\text{eff}}$ is the $f = 1$ Fourier component of the homonuclear dipolar-coupling constant. The fictitious spin-1/2 operators are defined as $S_z^\Sigma = (1/2) \cdot (S_{1z} + S_{2z})$, $S_x^\Sigma = (1/2) \cdot (S_1^+ S_2^+ + S_1^- S_2^-)$, and $S_y^\Sigma = (i/2) \cdot (S_1^+ S_2^+ - S_1^- S_2^-)$ where the z -axis (defining S_{1z} and S_{2z}) is along the applied rf-field. A rotation of the density operator from S_z^Σ to $-S_z^\Sigma$ leads to a full transfer of polarization from spin 1 to spin 2 assuming that no zero-quantum transitions take place.

The DREAM recoupling sequence has been used as the mixing scheme in two-dimensional correlation experiments (Figure 9a) and in the context of an efficient homonuclear spin-pair filter (Figure 9b) by combining different shapes for the adiabatic sweep. Such a filter is more efficient than a ‘sudden’ double-quantum filter since not all crystallites need to go through the double-quantum state $S_x^\Sigma \cos(\varphi) + S_y^\Sigma \sin(\varphi)$ at the same point in time. The different amplitude shapes and their corresponding receiver phase are shown in Figure 9c.

Figure 10 shows an application of the DREAM spin-pair filter to the suppression of natural abundance background signals in a mixture of the amino acids alanine, methionine, and *iso*-leucine. The C_α position of alanine was ^{13}C labelled, all other carbon atoms had natural isotopic abundance. The filtered spectrum (Figure 10b) shows only the alanine C_α, C_β spin-pair resonances, all other resonance are attenuated below the noise level. The efficiency of the selection of the adiabatic spin-pair filter is measured to be 61% from the intensity of the CH_3 resonance. The higher intensity of the (100% labeled) C_α resonance compared to the C_β

Figure 11 Two-dimensional ^{13}C chemical shift correlation spectrum of the cyclic decapeptide Antamanide using adiabatic DREAM mixing. The spectrum was recorded at a spinning frequency of $\omega_r(2\pi) = 40$ kHz at a proton Larmor frequency of 500 MHz. (Figure courtesy of Aswin Verhoeven)

resonance can be explained by intermolecular $C_\alpha-C_\alpha$ couplings that allow additional spin pairs to pass partially through the filter and is not due to incomplete suppression of isolated spins.

Figure 11 shows the application of the DREAM sequence as the correlation mechanism in a two-dimensional chemical-shift correlation spectrum. Due to the fact that it is a double-quantum mixing scheme the cross peaks show alternating negative and positive intensities. The spectrum was taken at a MAS frequency of $\omega_r/(2\pi) = 40$ kHz using an rf-field strength at the center of the sweep of $\omega_1/(2\pi) = 20$ kHz. Many dipolar recoupling sequences suffer from the fact that they are more difficult to apply at higher spinning frequencies since the rf-field has to be an integer multiple of the spinning frequency. For DREAM the required rf-field strength is only 1/2 of the spinning frequency which makes the DREAM method very well suited for application at high MAS frequencies. In fact, the method becomes more useful at higher MAS frequencies because the broadbandness of the DREAM mixing with respect to chemical-shift offsets increases linearly with ω_r . As a rule of thumb, the bandwidth of the sequence is approximately equal to $\pm\omega_r/4$. To cover an entire ^{13}C spectrum on a spectrometer with 400 MHz proton resonance frequency, a spinning frequency of about 35 kHz is required.

1 INTRODUCTION

At its most elementary level, nuclear magnetic resonance has three characteristic features that make it uniquely suitable for the identification of materials or compounds in chemistry, biology, and medicine, *chemical shift*, *spin–spin coupling* and *signal intensity*. In the typical NMR experiment, the signal intensity is proportional to the relative abundance of the nuclei represented. However, products generated by radical pair reactions may show dramatically perturbed signal intensities shortly after their formation. Such products show transient signals with anomalous intensities in either absorption (A) or emission (E).^{1,2} These effects are induced as a result of magnetic interactions in radical or radical ion pairs on the nanosecond timescale. They are known as ‘chemically induced dynamic nuclear polarization’ (CIDNP).^{3–8} The CIDNP effects (and similar anomalies for electron paramagnetic resonance spectra)⁹ are closely interconnected with *magnetic field* and *isotope effects*, which cause the dependence of radical reaction kinetics and yields on the strength of the hyperfine coupling between a nucleus and an electron.¹⁰ These phenomena arise as manifestations of closely related physical mechanisms. They are brought about by the existence of two radicals or radical ions in close proximity to each other (in a ‘cage’) so that they constitute a ‘pair’. CIDNP, as well as magnetic isotope effects, are ‘induced’ by singlet–triplet transitions occurring within the ‘cage’ during the radical pair lifetime.

2 MECHANISM OF CIDNP GENERATION

Nuclear spin polarization effects can be induced by a variety of mechanisms, including magnetic interactions in radical pairs or biradicals, electron–nuclear cross relaxation in free radicals, or reactions with *para*-hydrogen. The following brief overview includes some aspects of radical pairs and their interactions in magnetic fields.

2.1 The Radical Pair Mechanism

The radical pair mechanism explains the generation of CIDNP effects on the basis of two principles: the rates of radical pair reactions depend on the electron spin multiplicity of the pair; and the intersystem crossing in a radical pair can be influenced by the spin states of nuclei interacting with the electron spin(s).^{6,11–14} Combined, these selection principles cause a ‘sorting’ of nuclear spin states into different products and result in characteristic nonequilibrium populations in the nuclear spin levels of geminate reaction products and in complementary nonequilibrium populations in the spin levels of free radical (‘escape’) products.

Radical pairs in solution can be characterized by geometric parameters such as distance or orientation, or by electronic and magnetic parameters such as electron spin multiplicity or exchange interaction. Concerning the electronic spin state, radical pairs (RPs) can be either correlated or uncorrelated; radical pairs generated by a single, well-defined event (geminate RPs) are correlated, whereas radical pairs formed by the diffusion of two independently generated radicals are uncorrelated. Pairs having antiparallel electron spins have singlet spin multiplicity (S), whereas pairs with parallel spins are triplet (T). In an external magnetic field, the energy level of a triplet radical pair is split by the Zeeman interaction into three sublevels, T_+ , T_0 , and T_- (Figure 1). The magnitude of the splitting is field (B_0) dependent; it equals $g\beta B_0$ (g is the electron g factor; β is the Bohr magneton). Because of the exchange interaction, $2J$, singlet and triplet radical pairs have slightly different energies; however, $2J$ falls off rapidly upon separation and can be neglected at distances greater than 1 nm, i.e., greater than a few molecular diameters.

Chemical reactions carried out under controlled conditions give rise to correlated (geminate) radical pairs. Thermal reactions typically produce S pairs, whereas photochemical reactions generate S or T pairs, depending on the spin multiplicity of the precursor state. Once generated, the radical pairs can recombine (couple) or disproportionate to give diamagnetic products (Scheme 1). This, however, depends critically on the spin multiplicity; coupling is allowed for singlet pairs but is, in almost all cases, spin forbidden for triplet pairs. Competing with these reactions is separation by diffusion, leading to solvent separated pairs; this process is accompanied by intersystem crossing. Solvent separated pairs have a finite probability to diffuse together again and to react with each other. Alternatively, they may separate and react with the solvent or another substrate to give radical transfer products. The lifetime of geminate pairs is 10^{-12} – 10^{-11} s,

Figure 1 Radical pair energy level diagram in a magnetic field

Scheme 1

Figure 2 Vector model of radical pair spin states

whereas that of solvent separated pairs is 10^{-9} – 10^{-8} s; free radicals may live as long as 10^{-4} s.

Because of the key role of spin multiplicity in determining radical pair reactions, intersystem crossing is of paramount importance. This transition can occur by several mechanisms; of these, loss of electron spin orientation by relaxation results in irreversible losses. In contrast, dephasing induced by differences in the electron Larmor precession (Δg mechanism), or because of hyperfine interactions between the unpaired electrons and nearby nuclei (hf mechanism), have the character of quantum mechanical oscillations; these mechanisms cause reversible dephasing. Intersystem crossing resulting from these interactions can be illustrated by a vector model describing the relative orientation of the electron spins in the magnetic field, B_0 (Figure 2).⁷ The electron spins precess with Larmor frequency [equation (1)]

$$\omega = g\beta B_0/h \quad (1)$$

The unpaired spins of a singlet pair precess with a phase difference of 180° ; their vector sum is zero (Figure 2). The total spin of a triplet equals unity; the vector sum of their projection onto the external field direction can have three values, +1, 0, or -1 , corresponding to the T_+ , T_0 , and T_- levels (Figure 2). The vector model illustrates that simple dephasing of the spin precessions can cause transitions between the S and T_0 states. For example, the electron spins of two radicals, $R_1\cdot$ and $R_2\cdot$, with different g factors, $g_1 \neq g_2$, will precess at different rates; the difference, $\Delta\omega_{ST0}$, is dictated by the difference, Δg , between the g factors [equation (2)].

$$\Delta\omega_{ST0} = \omega_1 - \omega_2 = (g_1 - g_2)\beta B_0/h = \Delta g\beta B_0/h \quad (2)$$

The hyperfine-dependent mechanism also contributes to intersystem crossing. Magnetic nuclei in one or both radicals also precess around the magnetic field axis, generating local

Figure 3 ESR spectra (left) and precession of electron spins of a radical pair, $R_1H\cdot$ and $R_2\cdot$, in a magnetic field ($g_1 > g_2$; $a_H > 0$; singlet precursor). The different orientations of the nuclear spin create two types of radical pairs with precession frequencies $\omega_1^+ > \omega_2$ ($M_I = +\frac{1}{2}$; left), causing rapid loss of singlet character, or $\omega_1^- \approx \omega_2$ ($M_I = -\frac{1}{2}$; right), causing the pair to maintain its singlet character

magnetic fields. The electron precession frequency, ω , is dictated primarily by B_0 , but the local fields due to nearby nuclei make small contributions. Since the nuclei are oriented parallel or antiparallel to the external field, they can increase or decrease ω , causing different degrees of dephasing for different nuclear spin states. Thus, $\Delta\omega_{ST0}$ will be changed by a value of $\pm a/2$ [equation (3)]

$$\Delta\omega_{ST0} = (g_1 - g_2)\beta B_0/h \pm \frac{1}{2}a_n \quad (3)$$

The vector model for a radical pair, with g factors $g_1 > g_2$, with one magnetic nucleus (1H in $R_1H\cdot$; $a_H > 0$), and generated from a singlet precursor, is illustrated in Figure 3.⁷ The different orientations of the nuclear spin result in the existence of two types of radical pairs. One type has substantially different precession frequencies, $\omega_1^+ > \omega_2$ ($M_I = +\frac{1}{2}$; left), leading to rapid loss of singlet character. For the second type of pairs the precession frequencies are similar, $\omega_1^- \approx \omega_2$ ($M_I = -\frac{1}{2}$; right); these pairs maintain their singlet character longer.

Upon reencounter, pairs which have conserved singlet character can recombine, leading to a product, R_1H-R_2 , in which the nuclear level $M_I = -\frac{1}{2}$ is overpopulated (Figure 4). On the other hand, pairs that have undergone intersystem crossing can only diffuse apart, forming free radical reaction products, R_1H-X , in which the nuclear level $M_I = +\frac{1}{2}$ is overpopulated (Figure 4).⁷ NMR transitions in the newly formed products occur in the direction towards restoring the equilibrium (Boltzmann) populations; the intensities will depend on the deviation from equilibrium. This model illustrates that products generated by different mechanisms will have opposite polarization. Similarly, a change in the sign of Δg or a , or a change in the initial spin multiplicity, will invert the signal direction.

The above effects are *net* effects; these are typically observed when the two radicals of the pair have sufficiently different g factors. When Δg is small or equal to zero, the so-called *multiplet* effect is observed, where signals representing a nucleus (or a group of magnetically equivalent nuclei) show both A and E. A population diagram illustrating this effect is shown in Figure 5.⁷ The pair consists of two radicals, $R_1H_1H_2\cdot$ and $R_2\cdot$, generated from a triplet precursor and with identical g factors, $g_1 = g_2$; one of the radicals has two nonequivalent protons ($a_{H_1}, a_{H_2} > 0$).

Figure 4 Recombination of and escape from the pair, $R_1H\cdot$ and $R_2\cdot$. The CIDNP effects, emission for R_1H-R_2 , enhanced absorption for R_1HX , arise because the nuclear spin levels of the products are populated at different rates

Figure 5 Two-spin energy levels and NMR spectra of escape and recombination products of a radical pair $R_1H_1H_2\cdot + R_2\cdot$. A schematic EPR spectrum of the two radicals is shown above the pair

The quantitative theory of CIDNP is developed to a state where the intensity ratios and absolute enhancement factors of CIDNP spectra can be computed on the basis of diffusion, reaction, and relaxation rates, and with characteristic parameters of the radical pair (initial spin multiplicity, μ), the individual radicals (electron g factors, hyperfine coupling constants, a), and the products (spin-spin coupling constants, J).^{7,11–14} The observed effects are optimal for radical pairs with lifetimes in the nanosecond range; on a shorter timescale, hyperfine-induced intersystem crossing is inefficient, whereas on longer timescales the polarization decays due to spin-lattice relaxation in the radicals.

CIDNP patterns induced via the radical pair mechanism may be more complicated than discussed above, because (1) they may reflect the magnetic parameters of more than one radical pair; (2) the polarization may be influenced by nearby, strongly coupled nuclei; or (3) the effects may be ‘distorted’ by relaxation or cross-relaxation phenomena. The involvement of two or more consecutive pairs has been delineated in several

Scheme 2

Scheme 3

specific cases. For example, one radical of a geminate pair may undergo a rapid radical transfer reaction, generating a new pair with conservation of spin multiplicity. This ‘pair substitution’ can transfer *net* effects induced in a nonsymmetrical pair to a symmetrical pair and to a coupling product. The resulting polarization is known as a ‘memory effect’. In an extreme case, the decomposition of benzoyl peroxide in the presence of methyl iodide leads to net emission for methyl benzoate, toluene, and ethane, all owing to the involvement of the (singlet) benzoyl–methyl pair and formed by four consecutive pair substitution processes (Pair 1–Pair 5 in Scheme 2).⁷

In some cases CIDNP effects can be induced in consecutive pairs, although neither pair by itself is expected to generate polarization. The thermal decomposition of acetyl benzoyl peroxide gives rise to net emission for both the methyl and phenyl signals of toluene; this effect is incompatible with the benzoyloxy–methyl pair (Pair 6 in Scheme 3) because the phenyl protons have no hyperfine interaction, as well as with the phenyl–methyl pair (Pair 7 in Scheme 3) because it has no Δg . The observed effects can be explained as ‘cooperative effects’; they can be reproduced accurately, if one considers the $S-T_0$ evolution as a continuous process throughout the lifetime of both radical pairs.¹⁵

Other deviations from the CIDNP effects expected from the examination of Δg and a_H may be caused by the presence of nuclei with strong hyperfine coupling constants (hfcs), particularly ^{13}C nuclei whose hfcs may exceed 100 G. The 1H enhancement factors induced in radical pairs generated by α -cleavage of $^{13}C=O$ labeled ketones may be enhanced or depressed relative to the analogous $^{12}C=O$ labeled ketones. The magnitude of the deviation depends on factors such as Δg , B_0 , and the hfcs, a_H and a_C , of the two nuclei under consideration. The quantitative theory accounts correctly for the observed effects.¹⁶

Finally, any comparison of enhancement factors induced in magnetically distinct nuclei must take into account the differences in spin-lattice relaxation times, as well as considering distortions due to cross relaxation. Cross-relaxation processes can be viewed as ‘CIDNP pumped NOE effects’; they induce polarization in nuclei which have no hyperfine interaction with the unpaired electron spin. Both scalar and dipolar cross-relaxation mechanisms have been established, generating in secondary nuclei either polarization of the same phase as that of the primary nucleus or the opposite phase.^{17,18}

These distortions impose important limitations on the interpretation of CIDNP results, particularly in attempts to delineate the electronic structures of reactive intermediates based on the polarization patterns of their reaction products (Section 4.5). All distortions due to relaxation phenomena can be eliminated by time-resolved experiments.¹⁹

2.2 CIDNP Effects at Low Magnetic Fields

Although CIDNP effects are studied most conveniently at the magnetic field of the spectrometer, effects induced at lower fields are interesting and have provided relevant information.^{7,20} At low fields, the Zeeman interaction becomes sufficiently small that S can mix with all three T levels. The polarization induced under these conditions differs from the high-field polarization. The Δg term is no longer pertinent; recombination and radical transfer products show the same polarization phase. On the other hand, S and T precursors still give opposite polarization, as do hfcs of opposite sign.

Interestingly, the polarization phase can change direction several times as a function of field strength. Photolysis of diisopropyl ketone in CCl_4 gives rise to polarized CHCl_3 , apparently by disproportionation of an isopropyl- $\text{CCl}_3\cdot$ pair (Pair 8 in Scheme 4); the most likely pathway involves pair substitution. Between 0.5 and 80 G CHCl_3 shows A; the polarization changes to E between 80 and 450 G, and again to A for $B > 450$ G. Another notable feature of low field CIDNP are ‘ $n - 1$ multiplets’. The multiplets of two groups of magnetically nonequivalent nuclei each show one line of zero intensity. For example, ethyl bromide generated by decomposition of propionyl peroxide in the presence of CCl_3Br at 0.5 G shows three lines at 3.2 ppm and two lines at 1.6 ppm. At fields above 20 G the ‘missing’ signals begin to appear.^{7,20} Low-field CIDNP effects have played an important role in the development of the CIDNP theory since they afford a stringent test for the dynamic models used, but have provided little information about reaction mechanisms.

2.3 Biradical Polarization

The interactions of two correlated electron spins may also lead to CIDNP effects when the two spins are linked by a chain, as in a biradical. Depending on the chain length, two different polarization types are possible. For sufficiently long chains, the exchange integral, J , is of comparable magnitude as A; in such a biradical S- T_0 mixing can induce CIDNP effects when a reaction channel other than recombination is available. The resulting CIDNP effects follow the rules for nonlinked pairs. Examples include the multiplet polarization induced in a decamethylene biradical or the net effects induced in a 1-acyl-12-benzyl biradical. The 1,10-biradical is generated in a complex reaction sequence by thermolysis of cyclohexane diperoxide; it gives rise to cyclodecane and

decene.⁷ The 1,12-biradical (**1**) is formed by photolysis of 2-phenylcyclohexanone-1,2- $^{13}\text{C}_2$; it can regenerate the starting material or couple in the *para*-position, forming a ring-expanded ketone (**2**). This example is particularly illustrative as it generates CIDNP effects only in the presence of radical scavengers. In CCl_4 , for example, chlorine abstraction by the acyl radical prevents the longer-lived biradicals from intersystem crossing and coupling.¹⁶

For biradicals with shorter chains, a different mechanism involving S- T_{-} mixing has been established. In a biradical with $2J \cong g\beta B_0$, the hyperfine interaction, a , can induce transitions satisfying the selection rules, $\Delta M_S = +1$ and $\Delta M_I = -1$.^{7,20} When the biradical is generated from a T precursor and forms products from the S state, pure net emission will result. The magnetic field dependence of the CIDNP effects observed for a series of biradicals reflects their average singlet-triplet splitting as well as the biradical lifetimes (Figure 6). The underlying photoreaction will be discussed in more detail in Section 4.4. The diradicals in which the radical centers are separated by tethers of five or more CH_2 groups are best documented; however, smaller diradicals have been detected by CIDNP, for example a 1,5-diradical is formed in the photolysis of camphor and cyclopentane-1,3-diyl is obtained from a bicyclic azo precursor.^{7,20}

2.4 The Triplet Overhauser Mechanism

A limited number of CIDNP phenomena have been ascribed to an alternative process, the triplet Overhauser mechanism. This mechanism requires the precise timing of four consecutive steps: (1) generation of an electron spin polarized triplet by preferential intersystem crossing from an excited singlet state to one triplet sublevel; (2) rapid transfer of the electron polarization to a radical or radical ion; (3) electron-nuclear cross relaxation during the lifetime of the radical intermediate; and (4) transfer of the resulting nuclear spin polarization to a diamagnetic species.^{21,22} The first two steps are unexceptional; they are the basis for many chemically induced dynamic electron polarization (CIDEP) effects.^{23,24} Although the electron relaxation of polarized triplet states occurs with half-lives $^3T_{1e} \approx 10^{-9}$ s, electron-transfer quenching reactions ($k_e \approx 2 \times 10^{10} \text{ M}^{-1} \text{ s}^{-1}$) at sufficiently high quencher concentrations ($[\text{Q}] \geq 10^{-1} \text{ M}$) can compete with this process. Hydrogen-abstraction reactions ($10^7 > k_H > 5 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$), on the other hand, are usually too slow; thus, cross relaxation was specifically eliminated in photoreactions of benzophenone and diphenylmethylenes with benzylic hydrogen donors.²⁵

The two crucial steps in this mechanism are the electron-nuclear cross relaxation and the transfer of nuclear polarization from the radical (ion) to the product. The rotational tumbling of a radical changes the orientation of the

Scheme 4

Figure 6 Normalized intensity versus field curves of aldehyde proton signals obtained upon photolysis of the C₇–C₁₁ cycloalkanones; all signals are in emission. (Adapted from data of Closs²⁰)

electron and the nuclear spin relative to the magnetic field, modulating the anisotropic hyperfine interaction. This process causes mainly dipolar transitions (W_2 , net change in spin quantum number: 2) and, to a lesser extent, electron and nuclear spin–lattice relaxation (W_e and W_n , respectively) and scalar cross relaxation (W_0 , net change in spin quantum number: 0). The efficiency of these processes is proportional to the square of the anisotropic hyperfine tensor, B_z^2 , and is a complex function of the rotational correlation time, τ_r [equation (4)].²⁶

$$W_2 \propto B_z^2 \tau_r / (1 + \omega^2 \tau_r^2) \quad (4)$$

Scalar cross relaxation can be induced more efficiently by rapid degenerate exchange or by an internal motion such as the rotation of a CH₃ or CF₃ group. Here, the efficiency is proportional to the mean square variation of the isotropic hyperfine coupling and the rotational correlation time of the methyl group [equation (5)].

$$W_0 \propto (\delta a)^2 \tau_r \quad (5)$$

The final step, degenerate electron transfer, is uniquely suited for an efficient transfer of nuclear polarization from the radical (ion) to the product; it allows rapid transfer of nuclear polarization while conserving the electron polarization of the radical ion. Because of the square dependence upon B_z or δa ,

the signal direction induced by this mechanism is independent of the sign of the hyperfine coupling, but is determined by the predominant mechanism of cross relaxation.

Because of the short lifetime of polarized triplet states ($^3T_{1e} \sim 10^{-9}$ s), only a narrow range of quencher concentrations is suitable for this mechanism. This is illustrated by the CIDNP effects observed during the electron transfer quenching of *p*-fluorotrifluoroacetophenone by dimethoxybenzene (Figure 7). The ¹⁹F signals of the aromatic F and of the CF₃ group show opposite signal directions due to predominantly dipolar (Ar–F) and scalar cross relaxation (CF₃), respectively.²²

2.5 *para*-Hydrogen-Induced Polarization

The third polarization mechanism is unrelated to those previously described. These effects are observed during homogeneous hydrogenation reactions, in which the atoms of *para*-hydrogen are added pairwise to alkynes or alkenes. These reactions do not involve radicals and occur without loss of spin correlation. Therefore, a separate acronym has been adopted to designate the phenomenon, *para*-hydrogen-induced polarization (PHIP).²⁷

The underlying mechanism is based on the fact that molecular hydrogen has four magnetic states: α, α ; β, β ; $\alpha\beta + \beta\alpha$ (*ortho*-hydrogen); and $\alpha\beta - \beta\alpha$ (*para*-hydrogen). At room temperature the four levels are populated virtually identically, but at lower temperatures *para*-hydrogen becomes more favorable. Appropriate catalysts can establish different equilibrium concentrations; at ~ 80 K, the *ortho/para* equilibrium reaches

Figure 7 Quencher concentration dependence of CIDNP effects observed during the electron transfer reaction between photoexcited *p*-fluorotrifluoroacetophenone (0.03 M) by dimethoxybenzene (reproduced by permission of Verlag Chemie from H. D. Roth, R. S. Hutton, and M. L. Schilling, *Rev. Chem. Intermed.*, 1979, **3**, 169)

Scheme 5

~1:1. When *para*-enriched molecular hydrogen is transferred pairwise to a substrate and yields a product in which the two nuclei are magnetically distinct, two of the resulting nuclear spin levels can be significantly overpopulated at the expense of the others.²⁸ The NMR spectra of the hydrogenation products will show polarization similar to the multiplet effects discussed in Section 2.1 though induced by an entirely different mechanism (cf., Figure 5).

PHIP effects were discovered when samples containing platinum group hydride complexes (e.g. Rh) and phenylacetylene (3), which had been stored at liquid nitrogen temperature under hydrogen, were thawed and introduced into an NMR probe to follow the ensuing reaction (Scheme 5).²⁷ Interestingly, a complementary experiment can be carried out with *ortho*-hydrogen that has been separated by low-temperature chromatography. The resulting PHIP effects are expected to show polarization of the opposite phase as observed for *para*-hydrogen, and they do indeed.²⁹

3 EXPERIMENTAL TECHNIQUES

The CIDNP method requires acquisition of an NMR spectrum during, or within a few seconds of, the generation of radical or radical ion pairs. The technique is applied mostly in solution, typically at ambient temperatures, mainly under

steady-state conditions. However, a few experiments have been carried out in the gas phase,¹⁰ at low temperatures,³⁰ and with modest time resolution.^{19,31}

Simple thermally-induced CIDNP experiments can be carried out without modification of the spectrometer. Thermal decomposition or rearrangement reactions are initiated by placing a sample in the preheated probe. The reaction can then be followed by scanning the appropriate region repeatedly. For best results, the temperature should be adjusted so that the reaction proceeds with a half-life of a few minutes. In special cases, when the nuclei under investigation have long spin-lattice relaxation times, longer half-lives also can be accommodated.

The photochemical generation of radical pairs offers definite advantages over thermal CIDNP experiments, but poses the problem of how to introduce the light into the probe. In some cases, quartz light guides have been immersed into the sample tube; however, irradiation perpendicular to the long axis of the tube appears to be more efficient. The superconducting magnets of high-field spectrometers can be modified for irradiation by a light guide along the insert. Appropriate light sources include mercury arcs (200–1000 W), xenon arcs, or assorted lasers. Typically, the light beam is collimated and guided by quartz lenses or light pipes into the probe. Use of a quartz insert significantly expands the range of the optical spectrum accessible for excitation and of substrates suitable for study.

The Fourier transform (FT) technique offers significant advantages, because it makes it possible to follow the time evolution of all affected signals at high resolution.¹⁹ With appropriate modifications, the FT method also allows microsecond and even submicrosecond resolution. Flash photolysis with CIDNP detection combines the advantages of time-resolved laser spectroscopy with the structural information content unique to CIDNP.^{19,31} The basis for the success of the time-resolved method is the fact that geminate processes are complete in a fraction of a microsecond, while combination of free ions and/or exchange reactions may take tens or hundreds of microseconds depending on concentration. An example is discussed in Section 4.4

On the other hand, the application of FT spectroscopy to CIDNP presents some problems because many spin systems respond in a nonlinear fashion to a series of strong rf pulses. Most significantly, pure multiplet effects vanish completely at a flip angle $\alpha = 90^\circ$. Therefore, considerably weaker pulses ($\alpha = 15^\circ$) have to be applied, diminishing the sensitivity of the experiment somewhat.¹⁹

When measuring low-field effects, the experiment is carried out in a secondary magnet and the sample transferred to a conventional spectrometer. This experiment has two principal problems: the reaction has to be interrupted reproducibly before the sample is transferred; and the transfer has to be rapid and reproducible because the polarization decays with typical spin-lattice relaxation times, T_1 .^{7,20} Photochemical reactions induced either by a pulsed laser or a conventional light source with a reliable shutter allow the reaction to be interrupted reproducibly. Use of either a flow system with an efficient mixing chamber or a falling-tube system ensures reproducible transfer times.^{32,33}

4 APPLICATIONS OF CIDNP IN CHEMISTRY

The CIDNP technique has found various applications in chemistry and has provided valuable information that was or is not available by any other technique. Typical applications include: (a) determining the mechanism of a reaction, i.e., establishing the involvement of a free radical process; (b) demonstrating the involvement of short-lived reaction products (enols, cyclononatetraene); (c) probing the nature of the reactive intermediate generating the radical pair, e.g., determining the spin multiplicity or the reactivity pattern of photoexcited ketones or carbenes; or (d) characterizing the spin density distribution of an intermediate. The patterns of signal directions and intensities observed for different nuclei of a reaction product can be interpreted in terms of the hyperfine coupling constants of the same nuclei in the radical cation intermediate.

4.1 Qualitative Sign Rules

The application of CIDNP as a mechanistic tool has been aided immeasurably by the development of two simple qualitative sign rules that allow the prediction of CIDNP net [equation (6)] or multiplet effects [equation (7)] from the knowledge of four or six parameters, respectively.³⁴ Alternatively, experimental CIDNP results can be used to derive one of the polarization determining parameters. The application of these rules requires a basic understanding of the underlying reaction and polarization mechanism.

$$\Gamma_{\text{ne}} = \mu \times \epsilon \times a_i \times \Delta g \quad (6)$$

$$\Gamma_{\text{me}} = \mu \times \epsilon \times a_i \times a_j \times J_{i,j} \times \sigma_{i,j} \quad (7)$$

The following convention is used for the signs of the individual parameters:

- μ + the pair is formed from a triplet precursor (**T**) or by an encounter of free radicals (**F**)
– the pair is formed from a singlet (**S**) precursor
- ϵ + for products formed by coupling or disproportionation ('in-cage')
– for products formed by cage-escape reactions
- $a_{i,j}$ + if the nucleus under consideration has a positive coupling constant
– if the nucleus under consideration has a negative coupling constant
- Δg + for the radical with the higher g factor
– for the radical with the lower g factor
- $J_{i,j}$ + if nuclei i and j have a positive spin–spin coupling constant
– if nuclei i and j have a negative spin–spin coupling constant
- $\sigma_{i,j}$ + when nuclei i and j belong to the same radical
– when nuclei i and j belong to different radicals
- Γ_{ne} + enhanced absorption, **A**
– emission, **E**
- Γ_{me} + the low field signal(s) of a multiplet shows E, whereas the high-field signal(s) shows A (**E/A**)
– the low-field signal(s) of a multiplet shows A, whereas the high-field signal(s) shows E (**A/E**)

The definition of the parameter ϵ requires comment. The key to this parameter lies in the electron spin dependence of the product forming reactions. Originally formulated to distinguish 'in-cage' from 'escape' products, it is clear that it differentiates between products formed in reactions with electron spin restriction (only singlet pairs can couple or disproportionate; $\epsilon > 0$) and those formed without spin restriction (typically radical transfer products; $\epsilon < 0$). In radical ion pair reactions, on the other hand, both singlet and triplet pairs can undergo reverse electron transfer in the geminate cage (Section 4.5). In this case, singlet coupling corresponds to $\epsilon > 0$, whereas $\epsilon < 0$ denotes triplet coupling. Yet another spin sorting mechanism has been documented for acyl–benzyl radical pairs in micelles. Here, recombination can be faster than decarbonylation for some pairs, whereas it is slower for others. Pairs that undergo intersystem crossing rapidly regenerate the starting material ($\epsilon > 0$); the other pairs also react by coupling but after decarbonylation, giving rise to a different product ($\epsilon < 0$). Clearly, the assignment of ϵ requires an understanding of the spin sorting process. As a general rule, early reactions of singlet pairs correspond to $\epsilon > 0$; delayed singlet or triplet coupling correspond to $\epsilon < 0$, even in the geminate cage.

4.2 CIDNP in Rearrangement Reactions

Many mechanistic applications of CIDNP deal with different rearrangement types, including molecular rearrangements proceeding via radical pairs, structural rearrangements of radicals, or rearrangements involving consecutive intermediates. In general, a molecular rearrangement is a conversion of the type shown in equation (7). M is a migrating group, whereas Q and T, charged or neutral, are the original and terminal centers between which the migration occurs.³⁵ The rearrangements proceed with varying degrees of retention of configuration at the migrating carbon and display varying CIDNP intensities. The polarization observed in these reorganizations constitute the most elementary application of the technique, where CIDNP is used as an indicator for radical intermediates.

The course of the (Stevens) rearrangement of ammonium ylides (e.g., **4**) has been studied in detail (Scheme 6); different substrates or reaction conditions result in varying degrees of retention in the rearranged product (**5**). The reaction is induced by the addition of a strong base, converting the ammonium precursor to the ylide which undergoes a thermal rearrangement; the product shows CIDNP effects of intermediate intensity. The results are compatible either with a radical pair mechanism with exceptionally fast pair recombination, or with concurrent pathways involving radical pairs as well as a concerted process. The second possibility appears to be more likely because quantitative CIDNP measurements showed that the experimental enhancement factors are only $\leq 25\%$ of the value expected for a reaction proceeding exclusively by the free radical pathway.³⁶

The photolysis of aromatic esters and ethers may result in intramolecular rearrangements generating substituted phenols. CIDNP studies suggest that the rearrangement of aromatic esters (photo-Fries) and the reorganization of phenyl ethers

Scheme 6

Scheme 7

(photo-Claisen) proceed via radical pairs generated from the excited singlet state.³⁷ Of special interest are results observed for the rearrangement of *p*-cresyl methallyl ether (**6**) (Scheme 7). The major product, a cyclohexadienone (**7**) is formed by coupling in the *para* position; the observed CIDNP effects support this assignment. A minor product formed by coupling in the *meta* position (**8**) showed the opposite signal direction; this was explained by coupling of triplet pairs followed by intersystem crossing and hydrogen migration, one of the rare examples of triplet recombination in neutral radical pairs.

When the aromatic group does not have a *para* substituent, the initially formed cyclohexadienones undergo rapid hydrogen shifts to yield the phenol isomers. However, under appropriate conditions, intermediates such as benzylcyclohexadienone have lifetimes in the range of several seconds, allowing the observation of their enhanced spectra. The identification of short-lived intermediates is an attractive application of the CIDNP method.

Several carbon radicals undergo skeletal rearrangements which can be followed by CIDNP. The thermal decomposition of cyclopropylacetyl peroxide in hexachloroacetone produces 4-chloro-1-butene, among other products. This conversion proceeds via cleavage of the peroxide bond, decarboxylation of the radicals so generated, and cyclopropylcarbiny (**9**) to butenyl (**10**) rearrangement (Scheme 8). The vinylic CH₂ group shows the strongest enhancement, although these protons have negligible hfcs in the buten-4-yl radical. The resulting effects are good examples of cooperative effects where the polarization is determined by two consecutive pairs preceding the product.⁷

Scheme 8

In other studies, CIDNP results failed to support previously suggested rearrangements or structures. Thus, the nonclassical structure (**11**) suggested for the β -bromoethyl radical requires identical hfcs for the α - and β -protons. However, the CIDNP effects observed during photolysis of Ph-CO₂-O₂C-CH₂CH₂-Br show opposite signal directions for the α - and β -protons for coupling as well as radical transfer products. This result supports a nonsymmetric radical such as (**12**) with $a_\alpha < 0$; $a_\beta > 0$.¹⁰

(11)

(12)

The CIDNP technique has been instrumental in documenting many additional skeletal rearrangements of radical cations. Perhaps the best known of these is the valence isomerization of quadricyclane radical cation (**13**) to that of norbornadiene (**14**).³⁰ The geometric isomerization of alkene radical ions will be discussed in Section 4.5

(13)

(14)

4.3 CIDNP in Carbene Reactions

Among the characteristic reactions of carbenes are additions to unsaturated bonds and 'insertions' into C-H, C-Cl, or O-H single bonds. Delineating the exact mechanism of a carbene reaction involves, inter alia, differentiating between one-step (concerted) mechanisms and alternative two-step sequences involving biradicals or radical pairs, and determining the spin multiplicity of the reacting carbene. The CIDNP technique has been applied to the abstraction-recombination reactions of many carbenes. The reaction of triplet diphenylmethylene with toluene proceeds by hydrogen abstraction and produces triphenylethane with A/E multiplet polarization. The same product is also formed by the thermolysis of triphenylazomethane. In this reaction an E/A multiplet effect is observed, because the fragmentation of the azo compound proceeds from the singlet state.

CIDNP effects observed during the reactions of the parent compound, CH₂, and several simple β,γ -unsaturated derivatives, viz., vinyl-, methoxycarbonyl-, cyano-, acetyl-, several phenylmethylenes, and cyclohexadienylidene, identified the spin multiplicity of the reacting carbene and established the reactivity pattern of both the singlet and triplet states.^{6,38} For example, both ¹CH₂ and ³CH₂ abstract chlorine atoms from CCl₄, but show significant selectivity in their reactions with CHCl₃. While ¹CH₂ abstracts chlorine atoms preferentially, ³CH₂ attacks the hydrogen exclusively. The CIDNP effects observed during the reaction of monosubstituted carbenes with CHCl₃ are ideally suited to probe the preference for H- versus Cl-abstraction (Scheme 9). Chlorine abstraction generates 2-substituted 1,1,2-trichloroethanes (**15**), whose pairs of doublets are readily differentiated from the sharp singlet of the 2-substituted 1,1,1-trichloroethanes (**16**) formed by hydrogen

Scheme 9

abstraction. The results shown in Figure 8 were generated by benzophenone-photosensitized decomposition of methyl diazoacetate in CHCl_3 . The singlet at 3.7 ppm is compatible with H-abstraction by triplet methoxycarbonylcarbene (^3CHX ; $\text{X} = \text{COOCH}_3$), whereas the pair of doublets at 4.5 and 5.9 ppm is due to Cl-abstraction by the singlet carbene (^1CHX ; $\text{X} = \text{COOCH}_3$). These results suggest that the triplet carbene undergoes intersystem crossing in competition with H-abstraction.³⁸

Related experiments were carried out with the heavy carbene analogs, dimethylsilylene and dimethylgermylene.^{39,40} These intermediates abstract benzylic or otherwise activated chlorine, bromine, or iodine atoms; the resulting radical pairs

Figure 8 ^1H NMR spectrum of methyl diazoacetate in trichloromethane (a) and the CIDNP spectrum observed during the photosensitized decomposition of the diazo compound (b). (Adapted from H. D. Roth, *Acc. Chem. Res.*, 1987, **20**, 343)

form coupling products or diffuse apart, generating radical transfer products. CIDNP effects observed during these reactions suggest the involvement of singlet intermediates; apparently the corresponding triplet states are not accessible under the reaction conditions. CIDNP effects observed during the photolysis of tribenzylstannyl chloride in benzene were rationalized via dibenzylstannylene.⁴¹

4.4 CIDNP During Photoreactions of Carbonyl Compounds

Extensive studies of the photochemistry of aldehydes and ketones have revealed several general primary photochemical processes including: cleavage of a C–C bond α to the carbonyl function (Norrish type 1 cleavage); abstraction of a hydrogen atom, either intramolecular from the γ -carbon generating a 1,4-biradical, or intermolecular from a suitable donor; capture of an electron from an electron donor generating a radical ion pair; and addition to unsaturated bonds, which may also lead to 1,4-biradical formation.²⁵ The processes involving radical pairs can be studied by CIDNP, but those involving 1,4-biradicals are not readily amenable to this technique. Although CIDNP has been observed in reactions proceeding via biradicals, effective S–T mixing has been observed only when the electrons are separated by at least three carbons (Section 2.2).

The Norrish type 1 cleavage of ketones is a classic example of a photoinduced homolysis reaction and has been studied in great detail. CIDNP studies confirmed that the cleavage in many ketones occurs from the triplet state, although several aliphatic ketones show evidence for the involvement of singlet as well as triplet precursors.³⁷ The involvement of dual states is supported by nonlinear Stern–Volmer plots. Significant polarization for cross coupling products indicates a high degree of cage escape, estimated to be as high as 99%. In some cases, however, a relatively high degree of cage return is indicated. For example, the ketone polarization generated by photolysis of dibenzyl ketone, was not affected by addition of the free radical scavenger tri-*n*-butyltin hydride (Pair 9).

Products arising by geminate pair recombination can be differentiated from those formed by free radical coupling by the time-dependence of their polarization. For example, the light-induced α -cleavage of deoxybenzoin generates polarized reactant by geminate recombination (E; Figure 9; trace B) and bibenzyl as a free radical product (A; trace A). At delay times $>1 \mu\text{s}$, both signals grow due to increasing free radical encounters. Addition of free radical scavengers, such as thiols, suppresses the free radical contribution but does not affect the in-cage polarization (trace C).³¹

The irradiation of cyclic ketones generates α -aroyl- ω -alkyl biradicals (17). These intermediates can recombine, regenerating the reactant, or disproportionate, generating acyclic products such as ω -unsaturated aldehydes (18) or ketenes (19) (Scheme 10). The polarization induced in these systems shows pronounced field-dependence (Figure 6). With

Figure 9 Normalized line intensities of bibenzyl (A) and deoxybenzoin (B) observed during the photolysis of deoxybenzoin as a function of delay time τ . The deoxybenzoin polarization in the presence of a (thiol) free radical scavenger is designated as C. (Adapted from data of G. L. Closs and R. J. Miller, *J. Am. Chem. Soc.*, 1979, **101**, 1639)

Scheme 10

increasing chain length, the average singlet–triplet splitting decreases and the polarization maximum is shifted to lower fields. The width of the curves reflects the lifetimes of the singlet states.

Ketones for which both α -cleavage and intramolecular hydrogen abstraction are unfavorable may react by intermolecular hydrogen abstraction. The hydrogen abstraction reaction by photoexcited benzaldehydes from diphenylmethanes was used to test the predictive power of the radical pair theory. The resulting CIDNP effects, ranging from pure multiplet to pure net effects (Figure 10), can be reproduced by Δg values ranging from 2.7×10^{-3} [Figure 10(a)] to -2.3×10^{-3} [Figure 10(e)], demonstrating elegantly the dependence of the CIDNP polarization pattern on the relative g factors (Δg) of the radical pairs.⁴²

Bimolecular reactions of photoexcited ketones may lead to the formation of short-lived diamagnetic products. Thus, hydrogen abstraction by dialkyl or aryl alkyl ketones from a phenol gives rise to ketyl–phenoxyl radical pairs whose disproportionation either forms short-lived enols or regenerates the starting ketone, depending on whether the hydrogen transferred to the phenoxyl radical comes from the O–H or the C–H group.³⁷

4.5 CIDNP in Radical Ion Reactions

The applications of CIDNP in photoinduced electron transfer reactions have elucidated the mechanistic details of important reactions and given insight into unusual short-lived radical cations.³⁰ The geometric isomerization of alkenes may be

Figure 10 CIDNP spectra (benzylic protons) of coupling products generated via hydrogen abstraction by photoexcited benzaldehydes from diphenylmethanes. (Adapted from data of G. L. Closs, C. E. Doubleday, and D. R. Paulson, *J. Am. Chem. Soc.*, 1970, **92**, 2185)

Scheme 11

initiated by an electron-transfer process and proceed via two divergent mechanisms. The isomerization of some donor olefins is illustrated by the chloranil-sensitized isomerization of *cis*- and *trans*-1-phenylpropene (Scheme 11); the polarization of the regenerated isomer is stronger than that of the rearranged alkene, and the reaction of the *cis*-isomer generates stronger effects than the reaction of the *trans*-isomer. These results support the rearrangement of the *cis*- and *trans*-radical cations (**20**) via a common (perpendicular) transition state.³⁰

When strong electron donors, viz., *N,N*-tetramethylphenylenediamine (**21**), react with *cis*- and *trans*-**20**, the two olefins show well-balanced CIDNP effects regardless of which is the reactant (Figure 11). The results suggest a different mechanism in which **20** serves as the acceptor. Because of its high reduction potential ($E_{A-/A} \approx -2.7$ V), the free energy of the radical ion pair lies above the triplet state of **20** ($E_T \approx 2.6$ eV), allowing both singlet and triplet pairs to recombine. Singlet pairs regenerate the ground state reagents ($\epsilon > 0$), whereas triplet pairs populate the olefin triplet state ($\epsilon < 0$). This type of triplet has a minimum near a perpendicular configuration to minimize the repulsive interaction between the unpaired spins. The perpendicular triplet state can decay to either isomer and, thus, is the key intermediate in the rearrangement.³⁰ The recombination of **20**^{•-} and **21**^{•+} is one of several well-established cases documenting the triplet recombination of radical ion pairs.

Figure 11 ^1H CIDNP spectra observed during the photoreaction of *N,N*-tetramethylphenylenediamine with *trans*- (left) and *cis*-1-phenylpropene (right). In each spectrum, the multiplet on the right represents the β proton of the *cis*-isomer whereas the multiplet on the left represents the β proton of the *trans*-isomer. (Adapted from data of H. D. Roth and M. L. M. Schilling, *J. Am. Chem. Soc.*, 1980, **102**, 4303)

In additional applications, CIDNP signal directions and intensities are used to derive the hyperfine coupling pattern of radical ions. The ^1H hfcs are related to carbon spin densities either by π,σ polarization (causing negative hfcs) or due to a hyperconjugative interaction (π,σ delocalization; causing positive hfcs).²⁶ Therefore, the pattern of CIDNP signal directions and intensities reveal the spin density distribution and, hence, structural details of the paramagnetic intermediates. The results are often unambiguous because NMR chemical shifts are usually well understood and the identity of the coupled nuclei is, thus, clearly established.³⁰

Determinations of hfc patterns are not limited to small molecules. Time-resolved CIDNP spectroscopy was applied successfully to determine the relative hfcs of radical ions derived from chlorophyll and derivatives.⁴³ The CIDNP effects are generated by a photoinduced electron transfer reaction; the effects observed with a $1\ \mu\text{s}$ delay yield signs and relative magnitudes of hfcs in good agreement with ENDOR results.

4.6 Probing Mechanistic and Structural Aspects of Biomolecules

Charge transfer plays a key role in the mechanisms of many significant biological processes. The resulting zwitterionic biradicals or radical ion pairs are suitable targets for CIDNP studies. Various aspects of biomolecules have been probed by this method; the applications range from in vitro studies of model reactions, involving inter- or intramolecular electron transfer, to probing the three-dimensional structure of globular systems by interaction with an external reaction partner.

Among the model reactions, the electron transfer photo-sensitized cleavage of thymine dimers was the first to be scrutinized by CIDNP. In fact, electron transfer from *cis,syn*-(*N,N*-dimethylthymine) dimer (**22**) to anthraquinone sulfonate was the first radical ion reaction for which CIDNP effects were observed;⁴⁴ the results indicated efficient electron transfer induced cleavage of **22**. More recent studies of dimers (**23**), in which the N-1 positions are linked by a trimethylene chain, provided clear evidence for the dimer radical cation as an intermediate in the cleavage reaction.⁴⁵

Other model studies have been carried out with the photosynthetic pigments. In these studies, the excited chlorophyll served either as an electron donor (e.g., towards a quinone) or as an acceptor.⁴⁶ All CIDNP effects observed must be ascribed to the chlorin triplet state as the reactive intermediate. Bifunctional molecules in which a tryptophan is tethered as a secondary donor to a chlorophyll molecule give rise to strong polarization for the amino acid residue.⁴⁷ However, the initial reaction clearly involves electron transfer to an external quinone, which is then followed by intramolecular electron transfer to the chlorin radical cation. Apparently the model systems have, so far, failed to reproduce the rapid charge transfer characteristic for the rigid photosynthetic reaction center.

Photoinduced hydrogen abstraction and electron transfer reactions can be applied for identifying structural features of biomolecules, such as proteins or enzymes. These macromolecules have globular structures with some amino acid residues on the surface, whereas others are contained in the bulk of the molecule. If an external acceptor, such as 3-carboxylumiflavin (**24**), is irradiated in the presence of such a biomolecule, accessible residues which can function as H- or electron donors may give rise to CIDNP effects.⁴⁸ Suitable residues include histidine (**25**), methionine, tryptophan (**26**), or tyrosine (**27**). The mechanistic aspects of the interactions between photoexcited lumiflavin and individual amino acid residues have been studied in detail and are well understood.⁴⁹ The observed effects (Figure 12) reflect the reaction parameters ($\mu, \epsilon > 0$), the hfcs of the aromatic ($a > 0$) and benzylic protons ($a < 0$), and Δg ($g_{\text{Trp}}, g_{\text{His}} < g_{\text{F}} < g_{\text{Tyr}}$). For optimal CIDNP observation, the background signals of the biomolecules were suppressed by presaturation techniques

Figure 12 Schematic ^1H CIDNP spectra induced during the photoreaction of a lumiflavin with histidine, tryptophan, and tyrosine. (Adapted from data of S. Stob and R. Kaptein, *Photochem. Photobiol.*, 1989, **49**, 565)

and the spectra accumulated by alternating light and dark pulses.

For example, bovine pancreatic ribonuclease A (13 700 Da) shows CIDNP for one histidine (His-119) and two tyrosine units (Tyr-76, -115). The His-119 function must be located in the active site of the enzyme, since the effect is suppressed by ribonuclease A inhibitor. Bovine pancreatic trypsin inhibitor (6500 Da) shows CIDNP for Tyr-10 and Tyr-21. These results show that the two Tyr residues are on the surface, in solution as in the crystal (based on X-ray studies). A weak emission line was assigned to the $\epsilon\text{-CH}_2$ group of Lys-41. Since lysine is CIDNP inactive (though $\epsilon\text{-N}$ -dimethyllysine is active), the effects were ascribed to dipolar cross relaxation, implying that Lys-41 is adjacent to Tyr-10.

Photoexcitation of the coenzyme flavin adenine dinucleotide (**28**) generates a biradical by electron transfer from

the adenine to the flavine moiety. The resulting CIDNP effects were studied as a function of magnetic field as well as pH. The complete absence of polarization at neutral pH was interpreted as evidence for stacking of the aromatic units. The field-dependent CIDNP curves observed at acid pH suggest the presence of at least two biradical conformers which slowly interconvert on the CIDNP timescale.³³

4.7 Miscellaneous Reaction Types

The preceding selection of CIDNP topics is obviously incomplete. Many reaction types giving rise to CIDNP effects could not be covered here because of space limitations. Perhaps the most notable omission is the area of organometallic reactions; we have mentioned only the PHIP phenomenon (Section 2.5).²⁷ Bimolecular reactions between alkyl lithium compounds and organohalides have played a significant role in the discovery and development of the CIDNP effect,^{2,50} and many thermal and light-induced bond homolysis reactions of organometallics also give rise to spin polarization phenomena.⁵¹

Studies of the early phases of polymer growth should be a natural application of the CIDNP method. In fact, the earliest case of spin polarization was observed during a polymerization initiated by the thermal decomposition of benzoyl peroxide.¹ As yet, few studies have addressed the aspect of chain growth;⁵² most studies do not go beyond the primary thermal or photochemistry of the free radical initiators. Finally, we have not treated, as has been the custom, peroxide decompositions in a separate section, but have discussed the subsequent radical pairs in the context of appropriate reactions.

5 PERSPECTIVE

Chemically induced dynamic nuclear polarization is an interesting phenomenon as well as a powerful tool for a broad range of mechanistic and structural problems. Its application has brought to light a rich variety of intermediates, especially in photoinduced reactions. The characterization of short-lived intermediates utilizes the unique information inherent in NMR chemical shifts of reaction products combined with the characteristic distortion of intensities due to CIDNP. These applications remain a promising prospect. Significant additional results can be expected in photoinduced

reactions, particularly in biomolecules and in studies utilizing time-resolved techniques. Although its time resolution cannot rival that of optical spectroscopy, CIDNP has the advantage of identifying the target species unambiguously. Finally, the early phases of polymer growth are a significant target, if the chains are intercepted by rapid chain transfer reactions.

1 INTRODUCTION

The development of cross polarization (CP) techniques, allowing the transfer of magnetization from a system of spins I with high abundance (e.g. ^1H , ^{19}F , and ^{31}P) to a system of spins S with low natural abundance (e.g. ^{13}C and ^{15}N) was a major step to *enhance the sensitivity* of these rare nuclei in solid state NMR.^{1–3} As the sensitivity thresholds for rare nuclear spins have been lowered, NMR has become available for extensive studies of solid materials.

A second problem peculiar to solid state NMR originates from the fact that, in solids, molecules or molecular groups are generally not subject to fast isotropic motions as they are in liquids. Consequently, NMR applied to solid samples, e.g. polycrystalline or amorphous materials, is characterized by spatially anisotropic spin interactions. The dominating interactions for spin- $\frac{1}{2}$ nuclei in solids are the direct dipole–dipole coupling between spins, and the magnetic shielding due to the electronic environment of a given nucleus, causing the chemical shift of resonance lines. The resulting spectra of polycrystalline or amorphous samples typically reveal broad lineshapes reflecting these anisotropic interactions. It was a major technical goal in NMR to invent techniques which play, at least in part, a role analogous to that of thermal motion in liquids, i.e. to average out or reduce the anisotropic contribution of the spin interactions. This averaging can take place either in spin space or in ordinary coordinate space,^{4,5} depending on the interaction. To remove homonuclear dipolar couplings, averaging in spin space requires the application of multiple pulse sequences (see **CRAMPS**). In order to eliminate broadening of resonance lines of rare S spins due to heteronuclear dipolar interactions with abundant I spins, rf irradiation near the Larmor frequency of I spins can be applied (heteronuclear high power decoupling³). The removal of line broadening originating from the chemical shift anisotropy (CSA) can be accomplished by averaging performed in coordinate space, i.e. by rotating the sample around a spatially fixed axis inclined by a specific angle θ_m , called the ‘magic angle’, relative to the

direction of the external field B_0 . Magic angle spinning (MAS) and some descendent techniques are nowadays well established and routinely included in high-resolution solid state NMR studies, allowing the identification of chemical environments by the isotropic chemical shift.

Fast sample rotation also affects homo- and heteronuclear dipole–dipole couplings.^{6,7} Because these interactions provide the physical basis on which polarization transfer between different spin systems occurs, they are here considered first in some detail (see Sections 2 and 3). Following these considerations, the influence of sample spinning on the CP process will be discussed (Sections 4 and 5). Because sample spinning may impose dramatic effects on the CP process, effects which are undesirable from an experimental point of view, the possibilities of circumventing some of these difficulties are reviewed in Section 6. Since the majority of applications are based on the spin lock, cross polarization technique, proposed by Hartmann and Hahn,¹ and Pines, Gibby, and Waugh,² the present article is concerned with this method.²⁸ For details of other techniques, such as adiabatic demagnetization in the rotating frame^{1,3} and the nuclear solid effect,^{8,12} the reader is referred to the literature (see also **Cross Polarization in Solids**).

2 MAGNETIZATION TRANSFER IN THE RADIOFREQUENCY ROTATING FRAME

Figure 1 shows the basic pulse sequence used in CP experiments.^{2,3} Initially, a 90° ($\pi/2$) pulse is applied at the resonance frequency ω_{0I} of the abundant I spins with magnetogyric ratio γ_I , creating transverse magnetization. In the subsequent time interval, denoted by τ_{CP} , the rf field (strength in angular frequency units $\Omega_{1I} = \gamma_I B_{1I}$) is applied parallel to the transverse I -spin magnetization, thus locking the magnetization in the direction of the B_{1I} rf field. Simultaneously, rf irradiation (strength $\Omega_{1S} = \gamma_S B_{1S}$) occurs at the resonance frequency ω_{0S} for the rare S spins with magnetogyric ratio γ_S , the initial transverse magnetization of which is zero. If the Hartmann–Hahn condition¹

$$\gamma_I B_{1I} = \gamma_S B_{1S} \quad (1)$$

Figure 1 Pulse sequence for standard cross polarization. Radiofrequency irradiation occurs at the Larmor frequencies ω_{0I} and ω_{0S} for I and S spins simultaneously

for the rf field strengths is satisfied, transfer of magnetization from the I -spin system to the S -spin system can take place during the cross polarization mixing time τ_{CP} , resulting in a build-up of transverse S -spin magnetization, which can be observed after switching off the rf field in the S -spin channel. During this acquisition period, the rf irradiation in the I -spin channel may continue to provide decoupling of the I - S dipolar interaction.³

The elementary process for cross polarization involves transitions of dipolar-coupled I and S spins, frequently called flip-flop transitions or mutual spin flips, because one spin is changing its state from a higher to a lower energy, while simultaneously a neighboring spin moves from a state with lower to a state with higher energy. If a solid, containing systems of spins I and S with different magnetogyric ratios γ_I and γ_S , is subjected only to the external magnetic field B_0 , then the energy levels for both systems are given by the Zeeman interaction in the laboratory frame. The splitting of energy levels (in angular frequency units) is different for I and S spins, and is equal to their respective Larmor frequencies ω_{0I} and ω_{0S} [Figure 2(a)]. Under these circumstances flip-flop transitions involving I - S spin pairs possess a vanishingly small probability rate, because the (virtual) photon which would be emitted during an I -spin transition could not be absorbed by an S -spin transition between Zeeman energy levels. This situation changes if rf fields are present for both spin systems [Figure 2(b)]. The total Hamiltonian of the two spin systems in the laboratory frame of reference becomes oscillatory time dependent due to the presence of rf fields. It is convenient to choose a frame of reference which is rotating with the applied rf fields (doubly rotating frame), generally known in quantum mechanics as the transformation from the Heisenberg operator representation to the interaction representation.⁹ In this frame the time dependence originating from the rf fields (frequencies ω_k , $k = I$ or S) vanishes¹⁰ for $\omega_k = \omega_{0k}$ (on-resonance). Identifying the new z axis with the direction of the rf field vectors B_{1I} and B_{1S} , the total spin Hamiltonian in this tilted rotating frame (TRF)^{3,13} with spin components $\hat{I}_{zk}$, $\hat{I}_{xk}$ for the spins I_k , $\hat{I}_z = \sum_k \hat{I}_{zk}$ and the spin

components $\hat{S}_z$, $\hat{S}_x$ for a single S spin is:

$$\begin{aligned}\hat{\mathcal{H}} &= \hat{\mathcal{H}}_I + \hat{\mathcal{H}}_S + \hat{\mathcal{H}}_{IS} \\ \hat{\mathcal{H}}_I &= -\Omega_{1I}\hat{I}_z + \hat{\mathcal{H}}_{II} \quad \hat{\mathcal{H}}_S = -\Omega_{1S}\hat{S}_z \\ \hat{\mathcal{H}}_{IS} &= 2 \sum_k D_k \hat{I}_{xk} \hat{S}_x\end{aligned}\quad (2)$$

where it has been assumed that both rf fields are in resonance with the I and S spins, respectively. $\hat{\mathcal{H}}_I$ denotes the Hamiltonian for the I -spin system, whereas $\hat{\mathcal{H}}_{II}$ and $\hat{\mathcal{H}}_{IS}$ are the I - I homonuclear and I - S heteronuclear dipolar Hamiltonians. The homonuclear dipolar couplings among S spins can be neglected, due to the low abundance of S spins. D_k denotes the dipolar coupling strength between spin S and spin I_k . The above Hamiltonian includes the two terms $\Omega_{1I}\hat{I}_z$ and $\Omega_{1S}\hat{S}_z$, which represent the Zeeman interaction in the TRF for I and S spins, respectively. The corresponding splitting of Zeeman energy levels in the TRF, therefore, is given by Ω_{1I} and Ω_{1S} , which are experimental parameters. Satisfying the Hartmann-Hahn matching condition $\Omega_{1I} = \Omega_{1S}$ [equation (1)] provides equal TRF-Zeeman splittings for both spin systems, such that an energy transfer can take place between I and S spins [Figure 2(b)].

3 CROSS POLARIZATION AND DIPOLAR COUPLING

It is instructive to consider first a simple system, consisting of an isolated dipolar-coupled I - S spin pair, providing some basic concepts necessary to show the impact which MAS has on cross polarization. The energy levels of the spin system, i.e. the possible total energies of both spins, are shown in Figure 3(a). $|++\rangle$, $|+-\rangle$, etc., denote product TRF-Zeeman spin-state vectors $|m_I, m_S\rangle$ (with magnetic quantum numbers $m_{I,S} = +\frac{1}{2}$ for the z -spin component parallel, and $m_{I,S} = -\frac{1}{2}$ for the z -spin component antiparallel to the rotating rf field). If dipolar couplings are not present and $\Delta\Omega = \Omega_{1I} - \Omega_{1S} = 0$, then Zeeman state vectors are eigenvectors of the TRF Hamiltonian. The two states with antiparallel spin orientations are degenerate (i.e. having the same energy). $\Delta\Omega \neq 0$ removes this degeneracy, the eigenstates are now $|2\rangle$ and $|3\rangle$. For small $\Delta\Omega$ the magnetic quantum numbers m_I and m_S are still ‘good’ quantum numbers. The presence of $\hat{\mathcal{H}}_{IS}$ leads to transitions between Zeeman states or, in general, between $|2\rangle$ and $|3\rangle$, and $|1\rangle$ and $|4\rangle$. In Figure 3(a) the probabilities of these transitions are labeled W_0 and W_2 . The same holds for $\Delta\Omega = 0$ for the Zeeman states $|++\rangle$, $|+-\rangle$, $| - + \rangle$, and $| -- \rangle$. The energy levels in the TRF, including the dipolar Hamiltonian $\hat{\mathcal{H}}_{IS}$ and $\Delta\Omega$ being non-zero, can be obtained from the Hamiltonian $\hat{\mathcal{H}}$ in equation (2) (with $\hat{\mathcal{H}}_{II} = 0$) by using a matrix representation with the Zeeman state vectors, and solving the eigenvalue problem for $\hat{\mathcal{H}}$. The transition probabilities W_0 and W_2 are then given as the square modulus of the corresponding matrix elements of the time evolution operator⁹ $\hat{U}(t) = \exp(-i\hat{\mathcal{H}}t)$. If the sum of the two rf fields, $\Sigma = \Omega_{1I} + \Omega_{1S}$, is large compared to their difference $\Delta\Omega = \Omega_{1I} - \Omega_{1S}$, and to the dipolar coupling strength D between I and

Figure 2 Energy levels of I and S spins (a) in the laboratory frame and (b) in the rf rotating frame

Figure 3 (a) Energy levels of an I - S two-spin system in the tilted rotating frame for matching ($\delta\Omega = 0$) and mismatching ($\delta\Omega \neq 0$) the Hartmann-Hahn condition; (b) Hartmann-Hahn matching curve for a nonrotating solid

S spins, and if, in addition, the quantity $\Delta\Omega$ (referred to in the following as Hartmann-Hahn mismatch) is small compared to D , then the flip-flop transition probability W_0 dominates. W_0 depends on the coupling strength D , and is much larger than W_2 :

$$W_0 \propto \frac{D^2}{D^2 + \Delta\Omega^2} \gtrsim 1, \quad W_2 \propto \frac{D^2}{D^2 + \Sigma^2} \ll 1 \quad (3)$$

for D , $\Delta\Omega \ll \Sigma$, and $\Delta\Omega \ll D$. In general, I - I dipolar couplings are present in the solid, giving rise to a broadening of the I -spin levels.^{11,12} With increasing mismatch $\Delta\Omega$, the two energy levels for the states $|2\rangle$ and $|3\rangle$ of the I - S spin system shift relative to each other [Figure 3(a)], and for $\Delta\Omega > D$ [equation (3)] and $\delta\Omega$ larger than the I - I dipole couplings, the transition probability W_0 decreases significantly.

An entirely isolated I - S spin system would periodically exchange magnetization between I and S spin. The presence of many spins interacting with each other introduces the statistical, or thermodynamic, aspect^{3,13,14} into cross polarization.

Under standard CP conditions (Figure 1) the initial I -spin magnetization is transferred irreversibly to the S -spin system. However, the behavior of the elementary flip-flop transition allows one to understand, at least qualitatively, the efficiency of CP under mismatch conditions ($|\Delta\Omega| \neq 0$), as illustrated in Figure 3(b). The polarization transfer is most efficient for $\Delta\Omega = 0$. Increasing mismatch leads to a gradual decrease of S -spin magnetization as long as the levels of the spin states $|2\rangle$ and $|3\rangle$ still overlap, originating from their finite width due to I - I dipolar couplings. CP becomes completely inefficient if the mismatch becomes larger than the I - I dipolar coupling strengths. The plot of S -spin magnetization obtained by CP versus mismatch $\Delta\Omega$ is called the Hartmann-Hahn or CP-matching curve, and is drawn schematically in Figure 3(b). As will be shown below, the CP-matching curve, as an indicator of efficiency for I - S magnetization transfer, is of utmost importance when combining CP and MAS.

The result that magnetization transfer conserving the total spin energy occurs predominantly for small mismatch $\Delta\Omega$ can be expressed by the selection rules

$$\Delta m_I + \Delta m_S = 0, \quad |\Delta\Omega| \leq D_{IS}, D_{II} \quad (4)$$

i.e. CP takes place via flip-flop transitions (total change of the magnetic quantum numbers m_I and m_S is zero). The second condition in equation (4) includes the broadening of TRF-Zeeman levels, leading to a CP-matching curve of finite width.

4 DIPOLAR COUPLINGS IN ROTATING SOLIDS

The dipolar coupling strengths D_{jk} between two spins j and k depend on their mutual distance r_{jk} and on the orientational angle ϑ_{jk} of the internuclear vector $\mathbf{r}_{jk}$ relative to the static field $\mathbf{B}_0$ (see also *Internal Spin Interactions and Rotations in Solids*):

$$D_{jk} = \frac{\mu_0 \gamma_j \gamma_k \hbar^2}{4\pi r_{jk}^3} \frac{1}{2} (3 \cos^2 \vartheta_{jk} - 1) \quad (5)$$

Spinning of the sample around an axis tilted by the angle θ_m relative to $\mathbf{B}_0$ leads to a periodic time dependence of the angle ϑ_{jk} with the frequency ω_r of rotation as shown in Figure 4. The time-dependent term $\cos \vartheta_{jk}(t)$ can be expressed as a function of the angles θ_m , θ_{jk} and $\omega_r t$, and the angle-dependent part of D_{jk} then reads

$$(3 \cos^2 \vartheta_{jk}(t) - 1) = \frac{1}{2} (3 \cos^2 \theta_m - 1) (3 \cos^2 \theta_{jk} - 1) + \frac{3}{2} \sin 2\theta_m \sin 2\theta_{jk} \cos(\omega_r t) + \frac{3}{2} \sin^2 \theta_m \sin^2 \theta_{jk} \cos(2\omega_r t) \quad (6)$$

Decomposing the time-dependent cosine terms into complex exponentials, the Fourier expansion (with Fourier coefficients $d_{jk}^{(n)}$) is obtained:

$$D_{jk}(t) = \sum_{n=-2}^{+2} d_{jk}^{(n)} [\exp(in\omega_r t)] \quad (7)$$

Figure 4 Coordinate frame of reference for a sample spinning around the axis ω_r , and the vector r_{jk} rotating with a polar angle $\omega_r t$

The first term on the right-hand side of equation (6) is time independent [Fourier coefficient $d_{jk}^{(0)}$ in equation (7)], and becomes equal to zero for $\theta_m = 54.7^\circ$ —this is called the ‘magic angle’. The other two terms in equation (6) show that sample rotation results in a modulation of the dipolar coupling strengths D_{jk} with spinning frequencies ω_r and $2\omega_r$ and an average value equal to zero. Therefore, under sample rotation the dipolar Hamiltonians $\hat{\mathcal{H}}_{II}$ and $\hat{\mathcal{H}}_{IS}$ become periodically time-dependent with the period $2\pi/\omega_r$ of sample rotation.

5 CROSS POLARIZATION IN ROTATING SOLIDS²⁸

As illustrated in Section 3, the CP rate, as a function of the transition probabilities of I – S flip-flop transitions, and the form of the CP-matching curve depend on the I – S and I – I dipolar coupling strengths. In order to proceed with the quantum mechanical model discussed above, the resulting time periodicity of dipolar Hamiltonians originating from MAS has to be included. For an isolated I – S spin system in the presence of sample spinning the problem can be solved, for example, using the Floquet formalism (see *Floquet Theory*).^{15,16} Within this theory, originally proposed as a general method for solving linear differential equations with periodic coefficients, an average Hamiltonian, called the Floquet Hamiltonian, can be derived by using the Fourier decomposition of the periodic time-dependent dipolar coupling strengths [equation (7)]. For very fast sample spinning (i.e. when the MAS frequency ω_r is comparable to or larger than the dipolar coupling coefficients $d_{jk}^{(n)}$, $n = \pm 1$ or ± 2), the flip-flop transitions responsible for I – S magnetization transfer are subject to conditions which are more rigorous than the selection rules given in equation (4), because they now include the MAS frequency ω_r .¹⁶

$$\Delta m_I + \Delta m_S = 0, \quad |\Delta\Omega + n\omega_r| \leq \frac{1}{2}d_{jk}^{(n)}, \quad n = \pm 1, \pm 2 \quad (8)$$

which means, that CP is possible for mismatch values $\Delta\Omega = \pm\omega_r$ and $\pm 2\omega_r$, and becomes small for $n = 0$ because of the disappearance of the zero-order Fourier coefficient $d_{jk}^{(0)}$ at the magic angle [see equations (5)–(7)]. From the conditions given in equation (8), it follows that the CP-matching curve,

Figure 5 CP-matching curves for various spinning rates for a solid with relatively weak dipolar couplings, e.g. hexamethylbenzene

being rather broad and featureless for a nonrotating solid [Figure 3(b)], splits into sidebands separated by the MAS frequency ω_r , as shown in Figure 5. For very fast spinning, maximum CP does not occur at $\Delta\Omega = 0$, as in the static case, but takes place at $\Delta\Omega$ close to the first and second-order sidebands. The widths of these sidebands depend on the dipolar coupling parameters $d_{jk}^{(n)}$ ($n \neq 0$), and on ω_r as increasing spinning rates provide a more complete averaging of dipolar couplings. The CP-matching curves shown in Figure 5 are calculated by means of a statistical theory,¹⁷ taking into account that: (1) in a solid, usually many I spins interact with each other; and (2) each S spin may be coupled to more than one I spin. The dipolar couplings are introduced as parameters, which represent average values for the I and S spin systems (so-called ‘second moments’¹²), while the spin dynamics are described by statistical spin-correlation functions.

Experimental evidence for the break-up of the CP-matching curve into a sideband pattern was first provided by Stejskal et al.¹⁸ for adamantane. Many other examples of CP-matching behavior under MAS have been found experimentally.^{19–22} Figure 6 shows the ^1H – ^{13}C CP matching curve for aromatic carbon in polycrystalline hexamethylbenzene (HMB) obtained at a spinning rate of $\omega_r/2\pi = 5$ kHz. In this experiment the

Figure 6 CP-matching curves for aromatic ^{13}C nuclei in hexamethylbenzene: (a) experimental curve obtained at $\omega_r/2\pi = 5$ kHz; (b) theoretical curve

proton rf field was fixed at $\Omega_{1H}/2\pi = 40$ kHz and the ^{13}C rf field was varied in the range $\Omega_{1S}/2\pi = 18$ to 57 kHz. Each experimental data point in Figure 6 represents an intensity value of the ^{13}C NMR line resonating at ca. 130 ppm (isotropic chemical shift relative to tetramethylsilane), attributed to aromatic carbon nuclei in HMB. The theoretical curve was obtained¹⁷ using values for the $I-I$ and $I-S$ dipolar coupling parameters determined from the internuclear distances and the crystal structure of HMB.

The appearance of sharp CP-matching sidebands at high spinning rates causes various experimental difficulties. First, the maximum of S -spin magnetization is not obtained at $\Delta\Omega = 0$, as for the static case. The mismatch has to be adjusted to one of the sidebands, the location of which depends on ω_r . Second, the sidebands become narrow at high MAS rates, requiring highly stable rf amplitudes Ω_{1I} and Ω_{1S} , and accurate spinning rates which have to remain constant over extended periods of time. Otherwise, slight deviations lead to dramatic losses of the CP enhancement for S -spin magnetization. Furthermore, the spectrum of the S spins may possess a variety of resonance lines with different resonance frequencies; for example, ^{13}C NMR spectra of organic solids very often reveal resonance frequencies over a range of 200 ppm, which leads to resonance offsets resulting in different mismatch values $\Delta\Omega$ for each resonance line. This means that some S spins are properly cross polarized, while other S spins with different $\Delta\Omega$ values due to resonance offsets are only weakly polarized. Any of the latter cases results in distortions of the relative intensities in CP MAS spectra.

6 MODIFIED CP EXPERIMENTS AND MAS

Because of the usefulness of the CP MAS technique, much effort has been made in recent years to develop methods which circumvent the experimental disadvantage originating from the Hartmann–Hahn condition under MAS. These methods can be grouped as follows:

1. Mechanical techniques, for example, off-magic angle spinning²⁰ and stop-and-go magic angle spinning.²¹
2. Techniques based on modifications of the standard CP rf-pulse scheme (Figure 1), including rf phase or amplitude modulation,^{16,23,24} or rf amplitude variation.²⁵
3. Alternative ways of magnetization transfer, for example, via the nuclear solid effect,^{8,12} or dynamic nuclear polarization.^{12,26}

The following brief discussion will focus on methods (1) and (2).

Off-magic angle spinning exploits the fact that the zero-order coefficients $d_{jk}^{(0)}$ of the Fourier expansion [equation (7)] become unequal to zero for spinning angles θ different from the magic angle θ_m , which should lead to an increase in the CP-matching centerband (at high spinning rates) and to a broadening of the center- and sidebands. Sardashti and Maciel²⁰ employed a CP technique, using the angle $\theta = 90^\circ$ during the CP period, and switching to the magic angle before starting acquisition of the NMR signal. According to equation (6), only centerbands and second-order sidebands appear in the CP-matching curve. A broadening of the center- and sidebands originating from the less severe averaging of $I-I$ dipolar couplings for $\theta \neq \theta_m$ is also observed in this experiment.

Figure 7 CP pulse sequence with simultaneous phase inversion

Stop-and-go sample spinning, proposed by Zeigler et al.,²¹ is even more straightforward in its attempt to avoid CP-matching sidebands. During the CP period the sample is not spinning, or it is slowed down, while during detection MAS is turned on. Both techniques require advanced mechanical capabilities for the spinner system, either being able quickly to switch the spinner axis or to turn the spinning on and off during the CP experiment.

A general way to improve the magnetization transfer under MAS conditions is based on modifications of the CP rf-irradiation scheme.^{16,23–25} One possibility²⁵ consists of applying stepwise rf-amplitude variations of the spin lock field [variable amplitude CP (VACP)], thus creating a whole series of slightly different Hartmann–Hahn matching conditions during one CP period. In this way an averaging over rf-amplitude mismatches is achieved, resulting in a remarkable smoothing of CP-matching curves. Another strategy, which may give an idea of the general philosophy involved, introduces an additional time dependence into the CP Hamiltonian [equation (2)] by periodically inverting the phases of the rf fields in the I and S spin channels simultaneously,^{16,23,24} synchronized with sample spinning (Figure 7). The time dependence of the TRF Hamiltonian then originates from: (1) the MAS modulation of the dipolar interactions, and (2) the modulation of the rf fields. One effect of this pulse sequence, which is important from a practical point of view, consists of averaging or compensating for $\Delta\Omega$ deviations due to rf inhomogeneities.^{24,27} The pulse sequence of Figure 7 has been shown to provide a significant broadening of the CP-matching curve.^{16,24} Improvements have been proposed¹⁶ leading to a whole new class of general amplitude-modulation CP (AMCP) schemes based on the study of detailed time dependences of the TRF Hamiltonian, and allowing the design of pulse sequences to restore CP-matching conditions under MAS, which are similar to those in nonrotating solids.

1 INTRODUCTION

A number of techniques exist for producing well resolved NMR spectra of solid samples. Some, including very rapid rotation about the ‘magic’ angle¹ of 54.7° and CRAMPS (see *CRAMPS*) multiple pulse irradiation, attempt to produce well resolved spectra of abundant nuclei such as ¹H or ¹⁹F. However, much greater success has been achieved in obtaining high-resolution solid state spectra of ‘rare’ NMR isotopes such as ¹³C and ¹⁵N. Typically, three techniques are combined: cross polarization² to increase signal strength and measurement repetition rate, heteronuclear decoupling³ to remove line broadening due to surrounding abundant spins, and magic angle spinning⁴ to eliminate chemical shift anisotropy (CSA) effects.

This article deals primarily with cross polarization in solids. Heteronuclear decoupling and magic angle spinning are briefly mentioned, but more detailed discussions of these techniques are presented in other articles (see *Magic Angle Spinning* and *Rotating Solids*).

2 STRATEGIES FOR ACHIEVING HIGH-RESOLUTION NMR IN SOLIDS

It is helpful to begin by considering the various interactions that occur in the solid state.⁵ In order of their relative magnitudes, the interactions may be summarized as follows:

1. *Quadrupolar* This is an interaction involving electric field gradients that occurs only for nuclei of spin quantum number greater than $\frac{1}{2}$. Since most important NMR nuclei, including ¹H, have spin- $\frac{1}{2}$, they are not subject to quadrupolar effects.
2. *Dipolar* This is the effect that the nuclear dipole field generated by each nuclear spin has on its neighboring spins, and it is the dominant interaction for abundant nuclei such as ¹H spins in solids. Dipolar interactions are often referred to as either ‘homonuclear’, for interaction between nuclei of the same species (e.g. ¹H–¹H), or heteronuclear, for interaction between nuclei of different

species (e.g. ¹H–¹³C). Due to rapid, isotropic molecular motion, dipolar interactions are averaged to zero in liquids, but do contribute to the longitudinal relaxation parameter T_1 .

3. *Chemical Shift Anisotropy (CSA)* The magnitude of the diamagnetic effect that surrounding electrons have on the nucleus usually depends on molecular orientation. The average, or isotropic, shift is observable in both liquids and solids. In addition, resonance lines for most solids exhibit an additional shift based on molecular orientation. For single crystals this is manifested as a dependence of the resonance frequency on orientation. For a powder sample, all orientations are represented simultaneously and the result is a broad CSA ‘powder pattern’. These powder patterns often overlap and cause loss of resolution.
4. *Isotropic Chemical Shift* In a liquid, rapid molecular reorientation allows only the average, or isotropic chemical shift to be observed. In solids, the same result is often achieved by rapid rotation of the sample about an axis tilted away from the magnetic field by 54.7°, often referred to as the ‘magic’ angle. Magic angle spinning is discussed in more detail in other articles (see *Magic Angle Spinning* and *Rotating Solids*).
5. *J Coupling* This is an indirect coupling of nuclei to each other, mediated by shared electrons. As such, it is a ‘through-bond’ coupling, and is of great importance in liquids. However, it is too weak to be observable in most spectra of solids.

Elimination of the direct dipolar interaction between nuclei is clearly the first step in achieving high-resolution NMR in solids. The dipolar interaction between a given pair of spin- $\frac{1}{2}$ nuclei, as expressed by the dipolar Hamiltonian⁶ $\hat{\mathcal{H}}_D$, can be written as

$$\hat{\mathcal{H}}_D \propto \left(\frac{1}{r^3}\right) (1 - 3 \cos^2 \theta) \text{ spin part} \quad (1)$$

where r is the internuclear distance, and θ is the angle that the internuclear vector makes with the magnetic field. The ‘spin part’ varies, depending on whether the two nuclei are of the same species (homonuclear) or different species (heteronuclear). For example, the spin part for two coupled ¹H spins is given by:

$$\text{Homonuclear spin part} = \{\hat{I}_1 \cdot \hat{I}_2 - 3\hat{I}_{z1}\hat{I}_{z2}\} \quad (2)$$

where the labels 1 and 2 refer to the two ¹H spins. On the other hand, the spin part for dipolar coupling between a ¹H and a ¹³C nucleus is given by:

$$\text{Heteronuclear spin part} = \{\hat{I}_z \hat{S}_z\} \quad (3)$$

where I and S refer to the ¹H and ¹³C nuclei, respectively.

Clearly, the dipolar interaction may be eliminated by causing any of the three terms in equation (1) to vanish. In some cases, rapid rotation of the sample about the magic angle can be used to eliminate the second term.⁷ However, for most rigid solids it is usually not possible to spin fast enough for this approach to be effective in eliminating dipolar couplings. For heteronuclear coupling, the spin part can usually be eliminated by strong rf irradiation of one of the nuclear

species,³ whereas for homonuclear coupling the spin part can sometimes be sufficiently reduced by the CRAMPS multiple rf pulse technique (see **CRAMPS**).

The most commonly used approach is to observe a nuclear spin for which the NMR active isotope has a low abundance. For these ‘rare’ spins, such as ¹³C, the homonuclear coupling is automatically eliminated since the large distances between NMR active nuclei cause the first term of equation (1) to be vanishingly small. At the same time, the heteronuclear interaction with surrounding abundant spins, usually ¹H nuclei, is eliminated by strong continuous rf irradiation³ of the abundant nuclei to cause the spin part given in equation (3) to average to zero. For powder samples, magic angle spinning is also applied to eliminate CSA broadening.

There are two important disadvantages associated with NMR of rare nuclei in solids, namely low sensitivity and, in most cases, long relaxation times. The low sensitivity is an obvious result of low natural abundance.

The long relaxation times,⁸ or T_1 values, are essentially due to an accident of nature. For spin- $\frac{1}{2}$ nuclei, the nuclear spin energy is coupled to the surrounding environment, or ‘lattice’, via locally generated time varying magnetic fields. The strength of the coupling, and therefore the rate at which the nuclear spins return to equilibrium, is governed by the magnetogyric ratio. Unfortunately, all of the spin- $\frac{1}{2}$ NMR nuclei with rare isotopic abundance have relatively low gyromagnetic ratios, and therefore long relaxation times, compared with the most commonly observed abundant NMR spins, namely ¹H, ¹⁹F, and ³¹P.

Low sensitivity can be improved by using a very high magnetic field, but the expense is often prohibitive and, for some nuclei, especially ¹³C, a very high field can make it difficult or impossible to eliminate CSA effects. Another approach is to enrich isotopically the rare nucleus to a higher abundance. This approach can be very successful for improving sensitivity and for spectral editing, but it can also be very time consuming and expensive. In addition, enrichment beyond approximately 10% can cause broadening due to dipolar interactions between the ‘rare’ nuclei.

T_1 can sometimes be reduced by introducing paramagnetic impurities⁹ into the sample, or in some cases by varying the sample temperature. However, these are inconvenient and specialized techniques.

The most commonly used method for increasing the sensitivity and experiment repetition rate when observing rare spins in solids is to transfer polarization from surrounding abundant spins, usually ¹H nuclei, to the rare spins. This is referred to as ‘cross polarization’. Cross polarization not only enhances the signal strength of the rare spins, but also allows the experiment to be repeated at a rate governed by the T_1 of the abundant spins.

3 THEORY OF CROSS POLARIZATION IN SOLIDS

At equilibrium, the degree of nuclear polarization P_0 depends on the strength of the applied magnetic field B_0 , the magnetogyric ratio γ , and the ‘lattice’ temperature T_L :²

$$P_0 \propto \frac{\gamma B_0}{kT_L} \quad (4)$$

where k is Boltzmann’s constant. The polarizations of different nuclear species will therefore be proportional to their magnetogyric ratios:

$$\frac{P_{0I}}{P_{0S}} = \frac{\gamma_I}{\gamma_S} \quad (5)$$

The key to understanding cross polarization in solids is the concept of mutual spin flips. This is a process whereby two coupled spins undergo simultaneous, opposite transitions in their spin states. Essentially, one spin makes a transition from ‘spin up’ to ‘spin down’, while the other goes from ‘spin down’ to ‘spin up’. This process occurs spontaneously among abundant nuclei in solids. Since the total polarization is unchanged, the process conserves energy, and the spin part of the homonuclear dipolar coupling contains appropriate mutual spin flip terms. In order to show this better, equation (2) can be rewritten in terms of raising and lowering operators:

$$\text{Homonuclear spin part} = \left\{ \frac{1}{2} [\hat{I}_+ \hat{S}_- + \hat{I}_- \hat{S}_+ - 2 \hat{I}_z \hat{S}_z] \right\} \quad (6)$$

Because of this process of mutual spin flips, which is often referred to as nuclear ‘spin diffusion’, abundant spins tend to maintain a uniform degree of polarization despite localized perturbations such as paramagnetic impurities. For this reason, they are often described as a ‘thermodynamic bath’ of spins with an effective spin ‘temperature’.

Of course, mutual spin flips do not occur between rare spins since they are not coupled to each other. Also, they do not occur spontaneously between nuclei of different species, since a mutual spin flip of this sort does not conserve energy, and the spin part given in equation (3) does not contain the necessary raising and lowering operators.

Cross polarization in solids is normally achieved by using rf irradiation to induce heteronuclear mutual spin flips. Since the abundant spins far outnumber the rare spins, this process causes the polarization of the rare spins to be made equal to that of the abundant spins. According to equation (5) this means that the polarization of the rare spins is increased by a factor equal to the ratio of their magnetogyric ratios. For coupled ¹H and ¹³C spins, the ratio is approximately 4. Due to relaxation phenomena and other imperfections, a polarization enhancement factor of 3 is more typically achieved.

The basic method for inducing mutual spin flips between different nuclear species was introduced by Hartmann and Hahn, and is commonly called ‘Hartmann–Hahn’ cross polarization.¹⁰ The pulse sequence is shown in Figure 1. An initial I -spin pulse places the I magnetization along the y axis in the I -spin rotating frame. This is followed by continuous irradiation along y in the I frame, together with simultaneous irradiation of the S spins. The rf power levels for the two nuclear species are adjusted such that the ‘Hartmann–Hahn’ condition is met:

$$\omega_{1I} \equiv \gamma_I B_{1I} = \gamma_S B_{1S} \equiv \omega_{1S} \quad (7)$$

In practical terms, this means that the length of a $\pi/2$ pulse is the same for both spin systems. During a few milliseconds of simultaneous irradiation, a substantial magnetization develops along the irradiation axis in the S -spin rotating frame. In

order to acquire a FID, it is then only necessary to turn off the rf on the S channel and observe the signal while the I -spin irradiation is continued for the purpose of heteronuclear decoupling.

Figure 1 Basic pulse sequence for Hartmann-Hahn cross polarization

Hartmann-Hahn cross polarization can best be understood by carrying out a few simple quantum mechanical manipulations. In the doubly rotating reference frame of the Zeeman interactions for spins I and S , the Hamiltonian for the system may be written as:

$$\hat{\mathcal{H}}_R = \omega_{1I} \hat{I}_Y + \omega_{1S} \hat{S}_Y + \beta_{IS} \hat{I}_z \hat{S}_z \quad (8)$$

where ω_1 is the rf nutation frequency, β_{IS} is a constant, and all other Hamiltonian terms such as chemical shift have been omitted for the sake of clarity. When the Hartmann-Hahn condition is matched, $\omega_{1I} = \omega_{1S}$, and equation (8) may be written as:

$$\hat{\mathcal{H}}_R = \omega_1 (\hat{I}_Y + \hat{S}_Y) + \beta_{IS} \hat{I}_z \hat{S}_z \quad (9)$$

The two terms in equation (9) do not commute, but if $\omega_1 \gg \beta_{IS}$ the situation can be further simplified by transforming to the frame of the interaction $(I_y + S_y)\omega_1$. The Hamiltonian in this frame is:

$$\begin{aligned} \hat{\mathcal{H}}_R^I &= \beta_{IS} [\hat{I}_z \cos(\omega_1 t) + \hat{I}_x \sin(\omega_1 t)] \\ &\quad \times [\hat{S}_z \cos(\omega_1 t) + \hat{S}_x \sin(\omega_1 t)] \end{aligned} \quad (10)$$

Keeping only the time independent, ‘secular’ part gives:

$$\hat{\mathcal{H}}_R^I = \frac{1}{2} \beta_{IS} [\hat{I}_z \hat{S}_z + \hat{I}_x \hat{S}_x] \quad (11)$$

which is the first order average Hamiltonian, and commutes with the major interaction $\omega_1(I_y + S_y)$.

The significance of $\hat{\mathcal{H}}_R^I$ can be better seen if both the I and S coordinate axes are tilted by 90° , such that I_z' and S_z' are parallel with the applied rf fields, i.e. they point along I_y and S_y , which is to say the axis of quantization has been changed to the direction along I_y, S_y . In this doubly tilted frame, the Hamiltonian becomes

$$\hat{\mathcal{H}}_R^{I'} = \frac{1}{2} \beta_{IS} (\hat{I}_x \hat{S}_x + \hat{I}_y \hat{S}_y) \quad (12)$$

which can be rewritten in terms of raising and lowering operators as:

$$\hat{\mathcal{H}}_R^{I'} = \frac{1}{4} \beta_{IS} (\hat{I}_+ \hat{S}_- + \hat{I}_- \hat{S}_+) \quad (13)$$

Clearly, mutual spin flips will occur under these circumstances, but they will occur between magnetization aligned along the y axes in the I and S spin reference frames. Note that if the Hartmann-Hahn condition is not met, there is no secular part in equation (11), and the effect of simultaneous irradiation will simply be to eliminate the heteronuclear coupling.

This simple quantum mechanical treatment applies strictly to an isolated pair of spins. In such a case, the result of Hartmann-Hahn irradiation is an oscillation of magnetization between the two spins. However, in most cases the I spin is coupled to a large number of other I spins via homonuclear dipolar coupling. This coupling to a ‘bath’ of I spins quickly damps out any oscillation and results in a smooth buildup of S spin magnetization along the y axis.

Note that a similar quantum mechanical treatment may be used to show that application of CW irradiation to two spins coupled by homonuclear dipolar coupling yields an effective Hamiltonian that remains dipolar in form but is rotated in spin space and reduced in magnitude by a factor of 2. The result is that CW rf irradiation slows, but does not quench, spin diffusion between the I spins.

The rate of polarization buildup in the S spins will be governed by the strength of the heteronuclear coupling and by the rate of I spin diffusion. The characteristic time for this process¹¹ is often called T_{CH} , emphasizing the fact that the method is most commonly applied to cross polarization of ^{13}C spins coupled to ^1H spins. At the same time that the S spin polarization is growing, the I spin polarization will tend to decay according to the characteristic ‘spin locked’ or ‘rotating frame’ relaxation time¹² $T_{1\rho}$. The competition between these two rates will determine what level of polarization enhancement is actually achieved, how critical the cross polarization time is, and how quantitative the resulting spectrum will be.

Figure 2 presents two ^{13}C spectra of glycine, both obtained with magic angle spinning and heteronuclear decoupling and equal numbers of scans. The first spectrum shows the sensitivity obtained without cross polarization, while the second shows the spectrum obtained using Hartmann-Hahn cross polarization. It can be seen from Figure 2 that a substantial increase in signal strength is realized, although not quite the theoretical increase of 4. Also, a slight perturbation in the relative intensities of the resonance lines is evident. This is due to different values of T_{CH} and $T_{1\rho}$ for the two

Figure 2 Comparison of ^{13}C MAS spectra for glycine obtained by (a) block decay (single pulse) with heteronuclear decoupling, and (b) Hartmann–Hahn cross polarization followed by heteronuclear decoupling

lines. When multiple scans are to be accumulated, an additional gain in sensitivity is realized due to the shorter relaxation time, or T_1 , of the ^1H spins in glycine as compared with the ^{13}C spins (approximately 3 s as compared to 30 s). Figure 3 presents the ' T_{CH} ' polarization curve for Hartmann–Hahn cross polarization of glycine. The effects of the competing T_{CH} and $T_{1\rho}$ time constants can easily be seen from the figure.

Figure 3 T_{CH} cross polarization curves for glycine

It should be pointed out that Hartmann–Hahn cross polarization can also be described in thermodynamic terms.¹³ The abundant I spins are treated as a 'bath', with a 'spin' temperature determined by the degree of polarization and the energy associated with a nuclear spin state transition, i.e. spin

'flip'. Although the S spins are not in direct contact with each other, they are also treated as if they were a thermodynamic bath, and their low abundance is incorporated by assigning them a very low heat capacity. During the Hartmann–Hahn cross polarization period, the I and S spins are quantized along y , and are said to have spin temperatures determined by their polarizations and the strengths of the applied rf fields. The Hartmann–Hahn irradiation has the effect of thermally connecting the two spin baths and, since the S spins have very low heat capacity, they tend to approach the I spin temperature. As the rf fields are equal (in units of 1/second), equal temperatures imply equal degrees of polarization.

It should also be pointed out that there are other methods of cross polarization in solids. One approach uses rf irradiation with adiabatically varied amplitude to transfer magnetization via a 'dipolar' polarization state.^{14,15} Another uses the 'Jener–Brockhard' pulse sequence to transfer polarization via multiple quantum states.¹⁶ Still others transfer magnetization using nonthermodynamic techniques similar to those commonly used for liquids.¹⁷ However, all of these alternative techniques have significant disadvantages in comparison with Hartmann–Hahn cross polarization, and none of them is widely used.

4 CROSS POLARIZATION AT HIGH SPINNING SPEEDS

As was mentioned in the introduction, cross polarization in solids is usually combined with magic angle spinning in order to eliminate chemical shift anisotropies, or CSAs. This combined experiment is often called CP MAS, and it is without doubt the most commonly used experimental method in solid state NMR.

In order completely to eliminate CSA effects, the MAS spinning rate must be faster than the width (in hertz) of the broadest CSA pattern in the spectrum. CSA magnitudes depend heavily on the nuclear species and chemical environment. For example, CSAs for ^{15}N and ^{29}Si are typically less than 20 ppm, while CSAs for ^{31}P can be as large as 300 ppm or more. For ^{13}C ,

Figure 4 Glycine ^{13}C spectrum with slow spinning MAS. The spinning sidebands approximately trace out the CSA pattern

Figure 5 Glycine CP MAS signal strength as a function of Hartmann–Hahn mismatch and spinning speed. The match condition breaks into mismatch sidebands as the spinning speed is increased

CSA widths range from a few parts per million for methyl carbons atoms to 150 ppm or more for rigid aromatic carbon atoms.

If the MAS spinning rate is smaller than the CSA width, the CSA pattern breaks into ‘sidebands’ that are spaced at the MAS rate and approximately trace out the CSA pattern.¹⁸ An example of this is presented in Figure 4 for glycine. A small number of sidebands can generally be tolerated, especially in highly crystalline samples like glycine that yield spectra with sharp lines. In fact, well resolved sidebands can be analyzed to extract the principal values of the CSA tensor.¹⁸ Nevertheless, it is usually desirable to minimize the occurrence of CSA spinning sidebands by spinning rapidly. Since the CSA width is proportional to the magnetic field strength, the need for fast magic angle spinning increases at higher fields.

MAS spinning above approximately 20 kHz is a difficult mechanical and materials problem, and it also interferes with cross polarization because it tends to suppress heteronuclear dipolar coupling. Although the spinning rate is rarely fast enough completely to eliminate dipolar coupling, it is often sufficient to cause the Hartmann–Hahn match condition to become very critical and inefficient. As the spinning rate increases, additional ‘match’ conditions appear,¹⁹ making it possible to cross polarize when the rf strength of one channel is mismatched from the other by either one or two times the spinning rate.

At very high spinning speeds, cross polarization under these special mismatched conditions remains relatively efficient, even when almost no cross polarization is possible under normal matched conditions. An example of this high speed spinning effect for ^{13}C in glycine is shown in Figure 5.

Figure 6 Pulse sequence using alternating π pulses to improve cross polarization during high speed MAS

Figure 7 Variable amplitude cross polarization pulse sequence as it was originally proposed. The 'stair step' rf amplitude variation may be replaced by other functions such as a ramp or 'sawtooth'

that will provide sufficient signal intensity and yet will not overly complicate the data analysis by introducing too many spinning sidebands. Typically, CP MAS spectra of ^{13}C are measured in NMR spectrometers with ^1H resonance frequencies of 200–300 MHz, and are rarely attempted above 400 MHz. MAS rates are usually kept in the range 4–8 kHz, although spinning up to 15 kHz and beyond is not mechanically difficult. Even under these optimum conditions, ^{13}C CP MAS spectra of rigid solids are rarely free of CSA sidebands.

Several methods have been proposed to improve cross polarization during high speed spinning. In some, the spinning rate²⁰ or even the spinning angle²¹ is changed between the cross polarization and signal detection phases of the experiment. Other approaches use 180° rf pulses to 'spoil' MAS dipolar suppression during the cross polarization²². A typical pulse sequence for this method is shown in Figure 6.

Figure 8 Glycine VACP signal strength as a function of Hartmann–Hahn mismatch and spinning speed.

Unfortunately, it is difficult to achieve stable and reproducible results using mismatched Hartmann–Hahn cross polarization, because the mismatched conditions are very critical and strongly dependent on the spinning rate.

Because of the problems associated with high speed spinning, it is often necessary to select a magnetic field strength

The technique that currently appears to offer the greatest promise for cross polarization at high spinning speeds is called 'variable amplitude cross polarization' (VACP).²³ A diagram of the experiment as it was originally introduced is shown in Figure 7. Essentially, the method depends on the fact that, in many cases, especially for ^{13}C in most

samples, the cross polarization rate T_{CH} is much faster than $T_{1\rho}$. Therefore, there is time to vary the rf levels over a range of values, essentially searching for one or more of the special mismatched Hartmann–Hahn conditions. At most rf settings, no match will occur and the I and S spins will simply remain ‘spin locked’. Hopefully, however, at least one of the rf level settings will be near enough to a mismatched Hartmann–Hahn condition to result in significant cross polarization.

For many samples, VACP works very well. An example is given in Figure 8 for glycine spinning at 15 kHz. For experimental convenience, the 'stair step' approach illustrated in Figure 7 is often replaced by a simple amplitude ramp, and the range of rf levels is made large enough to extend from the exact Hartmann–Hahn match to an offset of twice the MAS frequency. Typical VACP cross polarization times are 10–20 ms, as compared to 1–5 ms for traditional Hartmann–Hahn cross polarization.

5 SPECTRAL EDITING AND OTHER TRICKS USING CROSS POLARIZATION

Experiments that serve to identify what functional group a given resonance belongs to are commonly referred to as ‘spectral editing’ techniques (see *Spectral Editing Techniques: Hydrocarbon Solids*). This is because they normally cause certain lines in the spectrum to be suppressed or inverted. There are several variations of the Hartmann–Hahn cross polarization method that are useful for spectral editing. Two examples that identify CH₂ carbon resonances are reverse polarization,²⁴ which depends on differences in T_{CH} , and WIMSE,²⁵ which uses a sophisticated heteronuclear multiple pulse cross polarization technique known as ‘windowless isotropic mixing’ or ‘WIM’.²⁶ Whereas most spectral editing methods depend on differences in coupling strength or polarization time, WIMSE makes use of basic differences in spin dynamics. During WIM cross polarization the I spins are isolated from each other, and a dynamic rather than thermodynamic behavior results. A diagram of the WIMSE experiment is presented in Figure 9, and WIMSE spectra of solid gelatin are presented in Figure 10.

WIM cross polarization is also very useful for heteronuclear two-dimensional spectroscopy in solids.²⁷ A diagram of the WIM based two-dimensional HETCOR experiment is presented in Figure 11. During the first part of this experiment, the BLEW-24 and BB-24 multiple pulse sequences are used to suppress both the homonuclear and heteronuclear dipolar couplings. As a result, the I spins evolve only under

Figure 10 WISME spectra for solid gelatin showing only CH₂ resonances (top), carbonyl, CH and CH₃ resonances (middle) and all resonances (bottom)

Figure 9 WIMSE spectral editing pulse sequence

Figure 11 Two-dimensional HETCOR pulse sequence

the influence of resonance offset and chemical shift. The magnetization is then cross polarized to the S spins using WIM, and the S signal is detected. An example of two-dimensional HETCOR applied to ibuprofen is presented in Figure 12. Because WIM is used for cross polarization, peaks occur in the spectrum only at positions that correlate directly coupled ^1H – ^{13}C spins. If the usual Hartmann–Hahn method were used, rapid ^1H spin diffusion would occur during the cross polarization time, and ‘cross peaks’ would appear for all possible combinations of ^1H and ^{13}C .

A number of other methods have been used to isolate spin groups during cross polarization, including simultaneously applied CRAMPS pulse sequences,²⁸ frequency switched Lee–Goldburg irradiation,²⁹ and very rapid Hartmann–Hahn irradiation.³⁰ So far, WIM appears to be the most successful of these methods.

Figure 12 Two-dimensional HETCOR spectrum of ibuprofen. The one-dimensional spectra shown along the axes are a BR-24 CRAMPS spectrum (vertical) and a conventional CP MAS spectrum (horizontal) which were obtained in separate measurements

6 CONCLUSIONS

Hartmann–Hahn cross polarization is widely used to improve sensitivity and experiment repetition rate for rare spins in solids. Although some loss of quantitative information often occurs, the benefits usually far outweigh the disadvantages. At high MAS spinning speeds, cross polarization becomes problematic, but the recently introduced variable amplitude method appears to reduce greatly these difficulties in many cases. A variety of specialized techniques based on Hartmann–Hahn cross polarization have been developed, including spectral editing methods and pulse sequences that suppress spin diffusion during cross polarization.

1 INTRODUCTION

In solids containing both magnetic nuclei and unpaired electrons, polarization transfer can be obtained between the electron and nuclear spin systems by irradiating at or near the electron Larmor frequency. The result is an enhanced nuclear polarization and, henceforth, an enhanced NMR signal. This effect is called dynamic nuclear polarization (DNP).

Several mechanisms can be responsible for the DNP phenomenon. In 1953, Overhauser predicted that in metals the NMR signal could be enlarged by saturating the resonance line of the conducting electrons: the Overhauser effect.¹ Carver and Slichter² showed experimentally in metallic lithium that Overhauser's revolutionary concept was correct.

Later on, Abragam and Proctor³ and, independently, Jeffries⁴ and Erb et al.⁵ found the occurrence of a DNP effect in solids containing fixed, mutually more or less isolated, unpaired electrons: the solid state effect. Finally, a third DNP effect has also been observed: the thermal mixing effect, which is present when the concentration of (fixed) unpaired electrons is so high that the mutual dipolar interactions between the electrons become comparable to the other interactions between the electrons and their surroundings. Provotorov⁶ showed that in that case the electron spin system can be characterized by two polarizations: one associated with the population distribution over the Zeeman levels and one associated with the population distribution over the internal local magnetic fields which the electrons are experiencing. These polarizations may change if off-resonance irradiation is applied. Abragam and Borghini⁷ used the results of Provotorov and showed that when the polarization associated with the local fields is changed, the nuclear polarization changes as well, due to a coupling between these two polarizations induced by the irradiating microwave field: the indirect thermal mixing effect. Goldman⁸ remarked that this coupling could be present also in the absence of microwave irradiation, and its significance for DNP was shown by Buishvili:⁹ the direct thermal mixing effect. The thermal mixing effects become especially important

when the nuclear Larmor frequency is comparable to or smaller than the ESR line width.

In principle large NMR signal enhancements can be obtained via DNP, maximal of the order of the ratio of the gyromagnetic ratios of the electrons and the nuclei. For example, for protons this would result in an enhancement factor of 660, and for ¹³C nuclei this factor would be as large as 2600. In the earlier days of DNP this aspect was mainly used and applied for the production of polarized targets used in high-energy physics or to study magnetic ordering in the μ K region. However, during the past 15 years new applications have emerged as well. This has been achieved by combining DNP with modern solid state NMR techniques such as cross polarization (CP), magic angle spinning (MAS), and two-dimensional NMR spectroscopy. As a result, more detailed information about structures and dynamics of materials amenable to DNP NMR could be obtained than would have been possible without DNP.

DNP NMR spectroscopy can be applied successfully in a large variety of solid materials such as those in which the unpaired electrons occur naturally, e.g., in the form of dangling bonds, materials in which bond ruptures have occurred, e.g., resulting from pyrolysis or ionizing radiation, materials containing paramagnetic impurities, and materials doped with a suitable paramagnetic agent. In this paper several applications of DNP NMR spectroscopy in solid materials research will be given following a brief description of the DNP phenomenon. Finally, some future aspects of the technique will be discussed.

2 THEORY

Extensive reviews of the different DNP effects have been given elsewhere.^{10–14} Here we shall confine ourselves to a short treatment of the main features of DNP. We shall restrict ourselves to discussing only the Overhauser and the solid state effects. Hence we shall neglect the thermal mixing effects. The main reasons for this omission are that in many cases the Overhauser and solid state effects dominate, and that the overall features of the thermal mixing effects are not much different from that of the solid state effect. Moreover, the thermal mixing effects require a rather lengthy derivation, which is beyond the scope of this article.

As is necessary in the description of any NMR experiment, we have to start with the Hamiltonian. For an electron–nuclear spin system the relevant Hamiltonian is given by

$$\hat{\mathcal{H}} = -\omega_e \hat{S}_z - \omega_n \hat{I}_z + \hat{\mathcal{H}}_{ee} + \hat{\mathcal{H}}_{en} + \hat{\mathcal{H}}_{nn} \quad (1)$$

The first two terms are the Zeeman interactions of the electrons and nuclei, respectively, where $\hat{S}_z = \sum_{j=1}^{N_e} \hat{S}_z^j$ are the electron spin operators and $\hat{I}_z = \sum_{i=1}^{N_n} \hat{I}_z^i$ are the nuclear spin operators. The term N_e is the number of unpaired electrons and N_n is the number of nuclei. Furthermore, in equation (1), $\omega_e = \gamma_e B_0$ and $\omega_n = \gamma_n B_0$, where γ_e and γ_n are the magnetogyric ratios of the electrons and nuclei, respectively, and B_0 is the external magnetic field strength. Finally, $\hat{\mathcal{H}}_{ee}$, $\hat{\mathcal{H}}_{en}$, and $\hat{\mathcal{H}}_{nn}$ denote the spin–spin interactions between the electrons, between the electrons and the nuclei, and between the nuclei, respectively. For DNP, the most

important term in equation (1) is the so-called hyperfine interaction term $\hat{\mathcal{H}}_{\text{en}}$. In general, this term consists of two parts, the scalar interaction term $\hat{\mathcal{H}}_{\text{en}}^s$ and the dipolar term $\hat{\mathcal{H}}_{\text{en}}^d$. The scalar interaction arises from a finite electron spin density at the nuclear sites, either directly from the unpaired electron itself or mediated by bonding electrons polarized by the unpaired electrons.

Before describing the DNP phenomenon we first consider the energy level scheme of electron–nuclear spin pairs. For simplicity we restrict ourselves to nuclear spin- $\frac{1}{2}$ systems, with positive γ_n values. The result is then the simple four-energy-level scheme given in Figure 1. Also given are the nuclear and electron quantum numbers, m_n and m_e , respectively (for the electrons the highest energy state corresponds to $m_e = +\frac{1}{2}$, because γ_e is negative), and as usual we denote a state in which, for example, $m_n = +\frac{1}{2}$ and $m_e = -\frac{1}{2}$ by the notation $|+-\rangle$. Finally, the amount of nuclei in each state is denoted by N_{n1}, N_{n2} , etc. Then, defining $N_n^+ = N_{n2} + N_{n4}$ and $N_n^- = N_{n1} + N_{n3}$ as the total amounts of nuclei in the + and – states, respectively, we can define the nuclear polarization, P_n , as

$$P_n = \frac{N_n^+ - N_n^-}{N_n^+ + N_n^-} = \frac{N_n^+ - N_n^-}{N_n} = \frac{\Delta N_{12} + \Delta N_{34}}{N_n} \quad (2)$$

In Figure 1 the situation of thermal equilibrium is depicted, where the population distribution is governed by the Boltzmann distribution corresponding to the lattice temperature. Then P_n is defined as P_n^0 . Similar expressions can be given for the electron polarization, P_e , and its thermal equilibrium value, P_e^0 . It can easily be derived that in the high-temperature approximation, where $\hbar\omega_e/kT_L, \hbar\omega_n/kT_L \ll 1$, P_n^0 and P_e^0 are given by

$$P_n^0 = \frac{1}{2} \omega_n \hbar (kT_L)^{-1} \quad \text{and} \quad P_e^0 = \frac{1}{2} \omega_e \hbar (kT_L)^{-1} \quad (3)$$

Figure 1 The Zeeman energy level scheme of electron–nuclear spin pairs. The population distribution over the energy levels depicts the thermal equilibrium situation

where T_L is the lattice temperature. It follows from equation (3) that the thermal equilibrium polarization of the electrons is a factor γ_e/γ_n larger than that of the nuclei. It is this difference in polarization that is used in DNP, which we shall now consider.

2.1 The Overhauser Effect

The Overhauser effect occurs when $\hat{\mathcal{H}}_{\text{en}}$ is time-dependent on a timescale of the order ω_e^{-1} . Then $\hat{\mathcal{H}}_{\text{en}}(t)$ causes relaxation transitions between the various levels depicted in Figure 1, which, when combined with an irradiation at the electron Larmor frequency, results in a change in the nuclear polarization.

In order to illustrate this, we assume that the scalar interaction term, $\hat{\mathcal{H}}_{\text{en}}^s$, dominates. It can be shown that $\hat{\mathcal{H}}_{\text{en}}^s$ causes a relaxation transition between the $|+-\rangle$ and $| - + \rangle$ states of the electron–nuclear system, hence between the levels 1 and 4 in Figure 1. We shall call this relaxation rate W_{14}^s , which is given by $W_{14}^s = \frac{1}{2} \overline{a_{ij}^2} J(\omega_e + \omega_n, \tau_c)$; $J(\omega, \tau_c)$ is the spectral density function characterizing the time dependence, $\overline{a_{ij}^2}$ is the time-averaged value of a_{ij}^2 , where a_{ij} denotes the strength of the scalar interaction. As with all relaxation transitions, after some population distortion W_{14}^s restores the Boltzmann distribution between the energy levels connected by W_{14}^s , hence between levels 1 and 4. Now suppose that we are irradiating with a microwave field of amplitude B_1 and a frequency ω close to ω_e . This means that we are irradiating between the electron Zeeman levels 1 and 3 respectively 2 and 4 with an induced transition probability $W/2 = (\pi/2) \gamma_e^2 B_1^2 g(\omega - \omega_e)$, where $g(\omega)$ is the normalized lineshape function of the ESR line.

Suppose also that W is large enough to saturate the ESR line completely. Then in the stationary situation, the population distribution over the various levels becomes as given in Figure 2. Due to the saturating irradiation the population of level 1 becomes equal to that of level 3, and the population of level 2 becomes equal to that of level 4. Due to the relaxation transition, W_{14}^s , the Boltzmann distribution exists between the levels 1 and 4. As a result, the population differences between the nuclear Zeeman levels 1 and 2 respectively 3 and 4 is increased: the nuclear polarization is (positively) enhanced. The enhancement curve, which is the Overhauser enhancement factor as a function of the irradiation frequency ω , reflects the (saturated) ESR line, and is symmetrical about ω_e for symmetrical ESR lines. The enhancement becomes maximal for $\omega = \omega_e$. An Overhauser effect also occurs when the (time-dependent) dipolar electron–nuclear interactions, $\hat{\mathcal{H}}_{\text{en}}^d$, dominate. It can be shown that $\hat{\mathcal{H}}_{\text{en}}^d$ causes relaxation transitions between all four energy levels, so that the result becomes more complicated. However, it can be shown that often the relaxation transition between the levels 2 and 3 dominates, and the reader can easily convince himself that in this situation the nuclear polarization enhancement becomes negative.

The question arises under which circumstances we can expect to observe an Overhauser effect. As already stated above, a time-dependence in $\hat{\mathcal{H}}_{\text{en}}$ is needed with a correlation time of the order of $(\omega_e \pm \omega_n)^{-1} \simeq \omega_e^{-1}$, which in practice means that τ_c has to be of the order 10^{-11} to 10^{-12} s. In

Figure 2 The Overhauser effect due to the scalar electron–nuclear interactions. The population distribution over the energy levels depicts the stationary situation

solids, the molecular motions are almost never that fast, so that an Overhauser effect due to this type of motion is highly unlikely. However, other processes may occur in solids that do provide the required time dependence: (1) in conductors or semiconductors, the conducting electrons move very rapidly through the lattice, rendering the spatial coordinates in $\hat{\mathcal{H}}_{\text{en}}$ time-dependent on a fast scale (this explains the success of observing an Overhauser effect in metals²); (2) in solids with large amounts of unpaired electrons and/or with electrons with a delocalized electron density distribution, strong electron–electron spin exchange interaction may occur.¹⁵ These interactions, which arise from electrostatic Coulomb interactions, cause a time-dependence in the electron spin operator $\hat{S}$ occurring in $\hat{\mathcal{H}}_{\text{en}}$, and hence in $\hat{\mathcal{H}}_{\text{en}}$ itself. Also this time-dependence can be fast enough to fulfill the requirements for the Overhauser effect.¹⁰ An example is the Overhauser effect observed in graphite and other solids containing large aromatic clusters.

2.2 The Solid State Effect

The solid state effect occurs in solids with fixed paramagnetic centers and with electron–nuclear interactions that are time-independent or only slowly time-dependent, with correlation times typically larger than about 10^{-5} s. The presence of $\hat{\mathcal{H}}_{\text{en}}$ means that there exist, beside the external B_0 field, static local magnetic fields in the sample, partly oriented perpendicular to B_0 . It is well known from second-order perturbation theory that the result of such interactions is that the electron–nuclear states can no longer be described by the pure product functions given in Figure 1, but become mixed with other states. The admixture coefficient depends on the energy

Figure 3 The solid state effect due to the forbidden transition W^- . The population distribution over the energy levels depicts the stationary situation

difference between the levels corresponding to the states and increases with decreasing energy differences. Hence, in highest order, the mixture occurs between the states corresponding to the levels 1 and 2 respectively 3 and 4. The result is given in Figure 3, where q (and its complex conjugate q^*) denotes the admixture coefficient. It should be emphasized that q is small, typically of the order 10^{-3} to 10^{-4} . Nevertheless, these small admixtures have as an important consequence that irradiation with a frequency $\omega_e - \omega_n$ or $\omega_e + \omega_n$ leads to a nonzero transition probability between the levels 2 and 3 respectively 1 and 4.

In order to understand this we consider the effect of irradiating with a frequency $\omega_e - \omega_n$. If the eigenstates were not mixed nothing would happen, because the matrix element $\langle -- | \hat{\mathcal{H}}_{\text{rf}} | ++ \rangle$ is zero as the Hamiltonian $\hat{\mathcal{H}}_{\text{rf}}$ representing the rf irradiation is proportional to single spin operators. However, if the eigenstates are mixed, a small but nonzero transition probability is obtained because now nonzero matrix elements such as $-q \langle + - | \hat{\mathcal{H}}_{\text{rf}} | ++ \rangle$ occur. This is called the ‘forbidden’ transition, W^- . Similar results are obtained for irradiation at $\omega_e + \omega_n$, giving rise to a ‘forbidden’ transition W^+ . The quantities W^+ and W^- are given by

$$W^\pm = 2|q|^2 \pi \gamma_e^2 B_1^2 g(\omega_e - \omega \pm \omega_n) \quad (4)$$

The effect of irradiating at $\omega_e - \omega_n$ on the nuclear polarization is depicted in Figure 3. Here we have also incorporated the effect of the electron Zeeman relaxation rate, W_{ze} . Then, in the stationary situation, W_{ze} maintains the Boltzmann distribution between the electron Zeeman levels 1 and 3 with respect to 2 and 4, whereas W^- equalizes the populations of levels 2 and 3. The result is a positive enhancement of the nuclear polarization P_n : the solid state effect. In a similar way it can be shown that irradiation at $\omega_e + \omega_n$ leads to a negative enhancement of P_n . For symmetrical ESR lines the solid state enhancement curve, which is the enhancement factor as a function of the irradiation frequency ω , is antisymmetrical about ω_e . The enhancement becomes maximal for $\omega = \omega_e \pm \omega_n$.

In Figure 4 examples are given of enhancement curves due to the various DNP effects, including the effects of thermal mixing. As mentioned before we will not treat thermal mixing in any detail. Here we confine ourselves to remarking that,

Figure 4 The enhancement curves of the various DNP effects: curve 1, solid state effect; curve 2, indirect thermal mixing effect; curve 3, direct thermal mixing effect; curve 4, Overhauser effect. Reproduced by permission of Marcel Dekker, Inc., from R. A. Wind, in 'Modern NMR Techniques and Their Application in Chemistry', eds. A. I. Popov and K. Hallenga, 1991, p. 125

like the enhancement curve due to the solid state effect, the thermal mixing enhancement curves are antisymmetrical about ω_e for symmetrical ESR lines. The direct effect of thermal mixing becomes maximal when the offset frequency, $\omega - \omega_e$, is comparable to the ESR linewidth, whereas indirect thermal mixing gives a maximal enhancement for offset frequencies between those for which the direct thermal effect and the solid state effect become maximal.

2.3 Enhancement Factors

As already mentioned in the Introduction, in theory large DNP enhancement factors can be expected, of the order of γ_e/γ_n . However, in practice, several factors can limit the magnitude of the enhancement factor which is actually obtained. We shall illustrate this for enhancements by the Overhauser and solid state DNP effects (for a more general treatment the reader is referred elsewhere^{13,14,16,17}). For the Overhauser effect, we have already remarked that DNP enhancement can be positive or negative, depending on whether the scalar or the dipolar electron–nuclear interactions dominate. As a consequence, as in general both types of interactions are present, the enhancement is reduced and can become almost zero in unfavorable cases.

In the solid state effect, irradiation with a frequency ω can lead simultaneously to both forbidden transition probabilities W^- and W^+ . This is especially the case when the ESR linewidth is comparable to the ω_n , see Figure 5 (in fact, as is shown in the figure, irradiation can result in both the allowed transition probability, W , and the forbidden transition probabilities W^- and W^+). As W^- and W^+ result in enhancements of opposite sign, the result is a decreased solid state enhancement, the so-called unresolved solid state effect. This can occur especially for low γ_n nuclei, for which ω_n is small. (However, it can be shown^{13,14} that in these cases the enhancements due to thermal mixing increase, so that

Figure 5 The allowed and forbidden transition probabilities as a function of the offset frequency $\Delta = \omega - \omega_e$. Irradiation at Δ_0 simultaneously leads to W , W^- , and W^+

the overall enhancement can still be large.) Other parameters that determine the enhancements are the amount of unpaired electrons, N_e , which has to be relatively large; the ESR linewidth, which should be small; the electron spin–lattice relaxation rate, W_{ze} , which should be large; the amplitude of the microwave field, B_1 , which should be large; the external magnetic field, B_0 , which should be small in order to obtain appreciable forbidden transition rates (this is only important for the solid state effect); the nuclear Zeeman relaxation rate, which should be small; and the correlation time τ_c characterizing the time dependence in $\hat{\mathcal{H}}_{en}$. As has already been mentioned, if $\tau_c \approx \omega_e \approx 10^{-11}$ to 10^{-12} s, the Overhauser effect dominates, whereas the solid state effect is observed when $\tau_c \geq 10^{-5}$ s. For τ_c values between these limits, both effects are small; if electron–nuclear interactions exist with different time constants, both effects might be present. We shall encounter this situation later.

The author and others^{14,16,17} have given expressions for the different enhancement factors, from which the enhancements can be calculated if the various parameters mentioned above are known. For instance, for abundant-spin systems with large γ_n values and fixed paramagnetic centers, appreciable solid state enhancement factors (a factor 10 or more) can be expected under the following conditions: $N_e \geq 10^{24} \text{ m}^{-3}$; ESR linewidth $\leq 1 \text{ mT}$; W_{ze}^{-1} of the order of $\mu \text{ s}$; $B_1 \geq 0.03 \text{ mT}$; $B_0 = 1.4 \text{ T}$; nuclear Zeeman relaxation time $\geq 1 \text{ s}$. For rare-spin systems with small γ_n values, the enhancement factors are often at least an order of magnitude larger, which is mainly due to larger Zeeman relaxation times and an increased importance of the direct thermal mixing effect.¹⁴

It should be kept in mind, however, that these parameters are not independent of each other, and that large enhancements have been observed under completely different conditions. For instance, in natural diamonds a large ^{13}C enhancement factor of 200 is observed¹⁴ despite the small value of N_e ($\approx 10^{22} \text{ m}^{-3}$). The reason is the large carbon Zeeman relaxation time ($\approx 2000 \text{ s}$) occurring in this material.

3 APPLICATIONS OF DNP NMR

Both the DNP enhancement curves and the DNP-enhanced NMR spectra can be used to obtain detailed and often unique information about the chemical and physical properties of solid materials, and representative illustrations of such applications will be given in this section. All experiments that will be

described have been performed in an external field of 1.4 T, corresponding to an electron Larmor frequency of 40 GHz and nuclear Larmor frequencies of 60 MHz for protons, 15 MHz for ^{13}C nuclei, and 12 MHz for ^{29}Si nuclei. Elaborate descriptions of the experimental setups, including the probes have been given.^{18,19} All measurements were performed at room temperature.

3.1 The DNP Enhancement Curves

The symmetrical or antisymmetrical character of the DNP curve makes it possible to determine whether the electron–nuclear interactions are time-dependent, time-independent, or whether both types of interactions are present. This is illustrated in Figure 6, where are given the enhancement curves for ^1H and ^{13}C using DNP for a low-volatile bituminous coal. The ^1H DNP curve, Figure 6(a), contains both a symmetric and antisymmetric contribution, presumably because part of the electrons undergo rapid spin-exchange interactions whereas other electrons behave as fixed paramagnetic centers. The ^{13}C curve, Figure 6(b), is antisymmetric within experimental error, probably due to the much larger enhancements resulting from the static electron–carbon interactions, which overshadow the relatively small Overhauser enhancement. The occurrence of both the Overhauser and solid state effect in the ^1H DNP curves has been observed in a large variety of coals of different rank,²⁰ as well as in cellulose heat-treated in the temperature range 250–1000 °C.²¹ It was found that for heating temperatures above 275 °C unpaired electrons were formed as a result of band ruptures and a DNP effect was observed. In the lower temperature range, up to ca. 450 °C, the solid state and thermal mixing effects dominate, whereas, between 450 °C and 700 °C, it is mainly an Overhauser effect which is observed (above 700 °C no DNP effect may be measured because the ESR line becomes very broad). However, the DNP enhancement curves indicate that an Overhauser effect also

exists in the low temperature range, and that the solid state and thermal mixing effects are present for heating temperatures up to 500 °C. This is attributed to the small amounts of unpaired electrons undergoing rapid spin-exchange interactions at low temperatures, and behaving as fixed centers at the higher temperatures, respectively. In fact, it could be shown that the DNP curves could be used to detect fractions of electrons smaller than 1% either behaving as fixed centers or submitted to exchange interactions.

3.2 DNP and High-Resolution NMR in Solids

The increase in the NMR signal due to DNP can be used to reduce measuring times or to measure relatively small amounts of compounds. This ability is especially important for NMR spectroscopy on rare-spin species where, in the absence of DNP, long measuring times, several hours or more, are required in order to obtain an acceptable signal-to-noise ratio. In this section we shall give examples of such DNP NMR experiments.

In solids containing, besides unpaired electrons, both abundant spins and rare spins, the rare-spin polarization can be enhanced via DNP in two ways. (1) *Indirectly*, by first enhancing the abundant-spin polarization followed by a polarization exchange between the abundant and rare spins via cross polarization (CP). This is called the DNP CP (or DNP CP MAS when magic angle spinning is applied as well) experiment. In those cases where both the abundant spins and the electrons are homogeneously distributed in the sample, the spin diffusion among the abundant nuclei is generally strong enough to establish a single, average, polarization enhancement for all abundant nuclei, resulting, after CP, in an enhanced, undistorted, NMR spectrum of the rare nuclear spins. (In compounds where the electrons and/or the abundant nuclei are not homogeneously distributed, a distribution in DNP enhancements may also occur. As we shall see later, this effect can be used selectively to study interfaces and surfaces.) (2) The rare-spin polarization can also be enhanced *directly* via a polarization exchange between the electrons and the rare nuclei. This experiment, in which the rare-spin NMR signal is observed via a standard 90° rf pulse, will be called the DNP SP (MAS) experiment (SP = single pulse). Of course, in materials such as ceramics and diamonds, which do not contain abundant spins, DNP SP is the only possible technique. As the spin diffusion between rare spins is small, a distribution of enhancement factors often exists in the DNP SP experiment with larger enhancements for the nuclei in the vicinity of the unpaired electrons.¹⁴ This has the disadvantage that distortions can occur in the DNP SP NMR spectra, but has the (potentially powerful) advantage that this experiment makes it possible selectively to probe structures and dynamics near the unpaired electrons.

It should be noted that in solids containing both rare and abundant nuclear spins, even in a DNP SP experiment the rare spin polarization can also be enhanced indirectly via a polarization exchange with the abundant spins. This has been called the three-spin effect.²² This phenomenon is observed in cases that the rare-spin Zeeman relaxation is dominated by the interactions between the rare and abundant nuclear spins. Hence this effect is more likely to occur for rare nuclei remote from the unpaired electrons, where the electron–nuclear

(a): Result of an SP experiment; (b) and (c): Results of a DNP SP experiment without (b) and with (c) proton saturation. Reproduced by permission of the Academic Press from G. G. Maresch, R. D. Kendrick, C. S. Yannoni, and M. E. Galvin, *J. Magn. Reson.*, 1989, **82**, 41

interactions become weak. The three-spin effect arises from the nuclear Overhauser effect (NOE). This is similar to the Overhauser effect described in Section 2. The only differences are that NOE is caused by nuclear–nuclear interactions instead of electron–nuclear interactions, and that NOE is due to dipolar interactions only. It follows from Section 2 that NOE leads to a positive polarization enhancement of the rare-spin polarization if the abundant spin polarization is decreased via saturation (assuming that the gyromagnetic ratio of the nuclei is positive). However, if the abundant spin polarization is, for example, positively enlarged via DNP, the NOE enhancement of the rare spins becomes negative. Consequently, in a rare-spin DNP SP experiment, a positive direct enhancement from the electrons can be counteracted by a negative NOE enhancement. The three-spin effect is illustrated in Figure 7 where ^{13}C spectra are shown of a polymer consisting of small islands of *trans*-polyacetylene (PA) embedded in a matrix of polyethylene (PE). In *trans*-polyacetylene, $(\text{CH})_x$, unpaired electrons (the so-called solitons) are present, presumably arising from bond-alternation domain walls.²³ These solitons move rapidly over the chains at least part of the time, giving rise to an Overhauser effect.^{14,24} It follows that for the ^{13}C line around 20 ppm, which is due to the PE carbons which are

Figure 8 ^{13}C spectrum of *trans*-polyacetylene, obtained via ^1H – ^{13}C DNP CP MAS NMR. The main line at 135 ppm is due to the ^{13}C nuclei inside the $(\text{CH})_x$ chains; structural defects responsible for the other lines are indicated in the figure

for the major part remote from the solitons in the PA chains, the NOE effect leads to a negative enhancement in a DNP SP experiment without proton saturation. However, the ^{13}C line around 200 ppm is due to the carbons in the PA chains. Here the soliton–carbon interactions are so strong that the NOE effect is not observed. The three-spin effect can be avoided by partially saturating the abundant-spin polarization to such an extent that the polarization remains at its thermal equilibrium value.

We shall now consider applications of the DNP CP MAS and DNP SP MAS experiments.

3.2.1 Increase in Sensitivity

The increase in sensitivity due to DNP can result in dramatic decreases in the measuring time of an experiment. This can be used, for instance, for a fast (of the order of minutes) characterization of coal,²⁰ ceramics,²⁵ and diamonds,¹⁴ to perform two-dimensional experiments in a relatively short time²⁴ (in this latter case, a two-dimensional experiment is reported for PA which would have required a measuring time of 165 years without DNP!), or to detect small amounts of molecules. An example of the latter application is shown in Figure 8 where the (natural abundance) ^{13}C DNP CP MAS spectrum of *trans*-polyacetylene is shown. Despite the fact that the amount of material was small (8 mg), the ^1H enhancement was so large (27-times in this experiment), that a ^{13}C spectrum with an excellent signal-to-noise ratio was obtained in a relatively short time.²⁶ In fact, it can be determined that the small narrow line at 13 ppm, which is due to the methyl end groups of the polyacetylene chains, represents only 0.5% of the total amount of carbons, or 3×10^{16} ^{13}C nuclei.

3.2.2 Structures and Dynamics Near the Unpaired Electrons

An example of the type of local information that can be obtained via DNP is shown in Figure 9. In this figure, ^{13}C spectra are shown of *trans*-polyacetylene obtained after a few

Figure 9 ^{13}C spectra of *trans*-polyacetylene, exposed to air for 4 months, obtained via (a) DNP CP MAS NMR and (b) DNP SP MAS NMR

months of exposure of the sample to air. Figure 9(a) shows the result of a DNP CP MAS experiment on ^{13}C . Compared with Figure 8, it follows that extra lines are observed due to the formation of ethene oxide groups, oxygen bridges, hydroxyl groups, and carbonyl groups.²⁷ Figure 9(b) shows the spectrum obtained via a ^{13}C DNP SP MAS experiment. We observe here that only the carbons in the $(\text{CH})_x$ chains are detected. Hence in the latter experiment mainly the carbons in the chains below the surface are observed. These are not affected by exposure to the air.

Another type of local information that can be obtained via DNP SP MAS is the spin-density distribution of the unpaired electrons over the molecules.²⁶ An example of this possibility is the organic conductor $(\text{fluorantheny})_2\text{PF}_6$. At room temperature this material behaves as a one-dimensional metal where the conduction electrons move more or less freely along paths parallel to the molecular stacks.²⁸ The electron mobility is so large that only an Overhauser effect is observed in this sample.²⁹ The average enhancement for ^1H is positive. This means that the dominating electron–proton hyperfine interaction is scalar. As a consequence, the overall enhancement of the DNP CP MAS spectrum of ^{13}C is positive as well, and Figure 10(a) shows the result of such an experiment. However, completely different results are obtained in the DNP SP MAS experiment on ^{13}C , shown in Figure 10(b). Here some lines are enhanced positively, indicative of a dominant electron–carbon scalar interaction, and one line is enhanced negatively due to a dominating electron–carbon

Figure 10 ^{13}C spectra of $(\text{fluorantheny})_2\text{PF}_6$, obtained via (a) DNP CP MAS NMR and (b) DNP SP MAS NMR. Reproduced by permission of Marcel Dekker, Inc., from R. A. Wind, in 'Modern NMR Techniques and Their Application in Chemistry', eds. A. I. Popov and K. Hallenga, 1991, p. 125

dipolar interaction, whereas for the other lines the two DNP effects eliminate one another, resulting in a negligibly small enhancement. This phenomenon is due to the distribution of the electron density over the fluorantheny molecules, which is different at the different sites of the carbons, resulting in different ratios of the electron–carbon scalar and dipolar interactions. Hence, experiments utilizing DNP SP MAS can be used to determine the electron density distribution over the sites of the chemically different carbons.

Another application of DNP NMR in conductors is the determination of Knight shifts.²⁹ The Knight shift is proportional to the polarization of the conducting electrons. Hence, by saturating the ESR line, not only a signal enhancement due to DNP is obtained, but the Knight shift is suppressed as well. It has been shown²⁹ that for $(\text{fluorantheny})_2\text{PF}_6$ the Knight shifts in the various carbon lines could be separated from the 'ordinary' chemical shift.

3.2.3 Interfaces and Surfaces

An example of an interfacial study with DNP NMR is an investigation of an immiscible mixture of polycarbonate

Figure 11 ^{13}C CP MAS NMR spectra of polycarbonate/polystyrene blends (a) with and (b) without ^1H DNP. The difference spectrum (c) has two features: the intensity around 40 ppm is due to the sp^3 -hybridized carbons in PS whereas the intensity around 120 ppm arises from the carbons in the PC chains at the interface. Reproduced by permission of the American Society from M. Afeworki, R. A. McKay, and J. Schaefer, *Macromolecules*, 1992, **25**, 4084

(PC) and polystyrene (PS).^{19,30} The samples consisted of thin film blends in which the polystyrene was doped with the stable radical BDPA [1,3-bis(diphenylene)-2-phenylallyl]. The interfacial region of PC could then be studied by measuring the DNP enhancement of protons via ^1H - ^{13}C DNP CP MAS NMR. Figure 11 shows the results of such a measurement, carried out on a blend consisting of PC, which is labeled at the 3 and 3' ring positions with 99 atom% ^{13}C , and PS, which is ^{13}C -depleted in all phenyl ring carbons. In this way, interferences between the NMR resonances of the aromatic carbons of the two polymers, which are partially overlapping, were avoided, and the peak observed at 120 ppm was almost exclusively due to the ^{13}C -labeled sites in PC. As the unpaired electrons in BDPA behave as fixed paramagnetic centers, the DNP enhancement of ^1H is mainly due to the solid state effect. Figure 11(a) and (b) show the ^1H - ^{13}C CP MAS spectra obtained with and without ^1H DNP, respectively. It follows that the protons in PS, which are close to the unpaired electrons, are enhanced to the greatest extent (a factor of 20) and that there is also a small but noticeable enhancement for the protons in PC. This can be seen more clearly in Figure 11(c) where the differential spectrum is given. It has been shown^{30a} that the proton polarization in PC is enhanced due to direct polarization transfer from these protons to the electrons, and that the signal of ^{13}C in PC observed in the differential spectrum arises from a 60 Å region from the PC/PS boundary which is 2% of the PC film thickness. Moreover, the

Figure 12 ^{13}C spectra of a 14% ^{13}C -enriched CVD diamond film, obtained via (a) DNP SP MAS NMR, (b) SP MAS NMR, (c) ^1H - ^{13}C DNP CP MAS NMR, and (d) ^1H - ^{13}C CP MAS NMR. Reproduced by permission of the American Institute of Physics from H. Lock, R. A. Wind, and G. E. Maciel, *J. Chem. Phys.*, 1993, **99**, 3363

authors were able to show that the interfacial aromatic carbons in PC have less motion than that of the bulk-PC aromatic carbons. This was attributed to restricted interchain motions resulting from a more dense packing for the PC chains near the PS barrier.

An example of a surface that can be studied via DNP NMR is provided by an investigation of chemical vapor deposited (CVD) diamond films.³¹ Figure 12 shows ^{13}C spectra of a 14% ^{13}C enriched diamond film prepared by microwave-plasma-assisted CVD, using CH_4 and H_2 as feed gases.^{31b} During the formation of the diamond films, unpaired electrons occur in the form of dangling bonds, which can be used for DNP measurements. Figure 12(a) and (b) show the results of ^{13}C DNP SP MAS NMR and SP MAS NMR, respectively, illustrating the increase in sensitivity due to DNP (the ^{13}C DNP enhancement factor is 50). Figure 12(c) and (d) show ^{13}C spectra obtained via ^1H - ^{13}C DNP CP MAS and CP MAS NMR. A small percentage of protons (<0.1 atom %) is present at the intergrain boundaries of the diamond, and DNP can be used to enhance the proton signal (the enhancement factor is 25). It follows from Figure 12(c) that the hydrogenated diamond surfaces give rise to new resonances in the carbon spectrum (it was shown that the broad resonance at around 45 ppm actually consists of two lines), and the chemical shifts corresponding to these lines have been used to investigate the possibilities of different 'diamondoids', hydrogen-bearing carbon structures, occurring at the surfaces.^{31b}

4 SUMMARY, CONCLUSIONS, AND PERSPECTIVES

High-resolution NMR combined with microwave-induced DNP has resulted in new areas of rare-spin NMR studies in solids. In many materials large DNP enhancement factors have been observed, which made possible NMR experiments which could not have been performed without DNP. The maximum proton enhancement that has been measured in a probe capable of MAS was 60, carbon enhancements of a few hundred were no exception, and in a ceramic fiber a silicon

enhancement factor 1000 was reported.²⁵ Although the DNP enhancements were not so large in some other materials, it should be kept in mind that even smaller enhancements can be very useful as they cause a reduction in the measuring time proportional to the square of the enhancement. Besides increasing the NMR sensitivity, DNP can also be used for other purposes such as the study of the structures and dynamics near the unpaired electrons, the detection of small amounts of electrons undergoing strong exchange interactions or behaving as fixed centers, the determination of the mobility and the spin-density distribution of conducting electrons, the study of surfaces and interfaces, the determination of Knight shifts, and DNP-enhanced imaging.³² Finally, DNP NMR has been applied in a large variety of solid materials, such as doped polymers, coal, pyrolyzed materials, amorphous silica, organic conductors, semiconductors, natural and artificial diamonds, polymer composites, and ceramics.

However, it should be noted that many other possibilities for utilizing DNP NMR still remain to be explored:

1. Other types of radicals such as ions, nitroxide radicals, or radicals resulting from ionizing radiation.
2. Other materials; for example, experiments have already been started to explore the potential of DNP in zeolites, catalysts, and biomaterials.
3. High-resolution DNP NMR on quadrupolar nuclei.
4. High-resolution DNP NMR at different temperatures.
5. High-resolution DNP NMR at different pressures.
6. Combination of DNP with other high-resolution solid NMR techniques such as CRAMPS, fast MAS, DAS, DOR.
7. Combination of high-resolution NMR with different DNP techniques, which have been developed to increase the DNP enhancement factors and to improve the polarization transfer rates. Examples of these new techniques are the NOVEL (Nuclear spin Orientation Via Electron spin Locking) experiment,³³ which is an electron–nuclear analog of the CP experiment, and which provides fast polarization transfer (μ s); the integrated solid effect (ISE),³⁴ where DNP is combined with adiabatic rapid passage through the ESR line, resulting in increased enhancement factors; DNP in the nuclear rotating frame,³⁵ which reduces the polarization transfer time by several orders of magnitude and which can be used to avoid distortion in the CP spectra resulting from rotating frame relaxation effects; DNP in higher external magnetic fields,³⁶ which might improve the resolution of the NMR spectra, and nuclear polarization enhancement using light irradiation. Examples of the latter techniques are microwave-induced optical nuclear polarization (MIONP),³⁷ optically polarized xenon and other rare gases, which can be used to study surfaces³⁸ and optical nuclear polarization (ONP).³⁹ Large enhancements have been obtained; for example, by applying the ISE technique in a naphthalene crystal doped with pentacene, in which the triplet state is highly polarized by photo-excitation, a DNP enhancement factor of the naphthalene protons of 5500 has been found.⁴⁰

It can be expected that this and the other new methodologies and applications will further enhance the applicability of solid state NMR, and that many exciting new results will emerge in the near future.

1 INTRODUCTION

The term ‘pulsed electron–nuclear multiple resonance’ (PE NMR) spectroscopy refers to a broad range of experimental methods in which pulsed NMR techniques are combined with pulsed electron paramagnetic resonance (EPR) techniques. This combination provides the capability to measure the spectra and spin dynamics of nuclei which are magnetically coupled to unpaired electrons by the hyperfine interaction. Related experimental techniques for measuring the interactions of nuclei coupled to unpaired electrons are paramagnetically shifted NMR, dynamic nuclear polarization (DNP), electron spin resonance (ESR), the pulsed ESR technique of electron spin echo envelope modulation (ESEEM), and continuous wave (CW) electron–nuclear double resonance (ENDOR). These techniques are complementary rather than competing methods for measuring different aspects of the magnetic interactions of the coupled electron–nucleus spin system. Each technique offers certain advantages as well as certain limitations. The most appropriate experimental approach for a given problem also depends on the type of information desired.

The PE NMR techniques discussed in this article are best suited for measuring the magnetic interactions of nuclei in the local coordination structure of a paramagnetic electron. A distinguishing characteristic of nuclei which are detected in PE NMR experiments is that the NMR transition frequencies are shifted by very large values when compared with NMR spectra of diamagnetic samples. These large shifts arise from the large local magnetic fields originating from the unpaired electron spins. Consequently, the resonance frequency is described by the hyperfine coupling and is measured in units of kilohertz or megahertz as opposed to a resonance frequency shift of parts per million referenced to the nuclear Larmor frequency of a standard.

Nuclei which experience large local magnetic fields originating from unpaired electrons are encountered in a wide spectrum of research areas, including chemistry, materials science, polymer science, environmental science, and the biological sciences. Specific examples include: organic and inorganic radical molecules;^{1–3} fossil fuels;^{4,5} organic conductors, semiconductors and electroactive polymers; organometallic transition metal complexes;^{6,7} dopants and other localized states

in semiconductors;⁸ surfaces such as on oxides and semiconductors; at the internal interfaces of semiconductors, superlattice structures, polymers, and composite materials; catalysis; transition metal ions in zeolites; and at the active sites for electron transfer or substrate binding in metalloproteins and metalloenzymes.⁹

If the unpaired electron spins can be treated as independent (or only weakly coupled) dipoles, their magnetic susceptibility is described by paramagnetism. Nuclei which sustain a hyperfine coupling with such electrons are therefore also referred to as paramagnetically coupled nuclei. Under certain conditions the NMR spectrum of paramagnetically coupled nuclei can be observed directly in the NMR spectrum as a paramagnetic shift. This is usually identified by the magnitude of the frequency shift and its temperature dependence. The local magnetic field originating from the unpaired electron spin shifts the NMR frequency and broadens the linewidth for those nuclei which sustain a hyperfine interaction. Both the magnitude of the frequency shift and the linewidth depend on the magnitude of the hyperfine coupling and on the details of the spin dynamics, specifically on the spin relaxation rates of the electron and nuclei. Well-resolved NMR lines can be observed if the electron spin–lattice relaxation time T_{1e} , or electron spin correlation time τ_e , which describes the time dependence of the local magnetic field, is short enough to assure that the orientation dependence of the local field is time averaged to its isotropic value. The paramagnetic shift is then determined by the isotropic hyperfine coupling arising from the unpaired spin density on the nucleus. Several texts have been written which describe the theory and applications of NMR to paramagnetic molecules including proteins and enzymes with paramagnetic transition metal ions.^{10–12}

The short electron spin relaxation time required to observe paramagnetically shifted nuclei directly in NMR spectra also typically result in very broad ESR linewidths. In fact, as a rough guide, paramagnetically shifted NMR transitions are usually only observed in cases where the ESR spectrum is too broad to be observed. However, very broad ESR linewidths can also originate from inhomogeneous line broadening, even if the electron spin relaxation times are very long. In either case, if an ESR spectrum is observed, several experimental approaches are potentially applicable for the measurement of the magnetic interactions of the hyperfine coupled nuclei in these cases. These include DNP, ESR, ESEEM, ENDOR, and the extension of the latter to PE NMR.

In DNP spectroscopy the hyperfine coupling is used as a mechanism to enhance the nuclear polarization. The details of the mechanism for this enhancement and the magnitude of the enhancement depend on the details of the hyperfine interaction, particularly on the time dependence of the hyperfine coupling, and on the details of the ESR spectrum, such as the ESR linewidth and relaxation time. The theory and applications of DNP spectroscopy have been discussed in several texts and review articles.^{13–18} (See *Dynamic Nuclear Polarization and High-Resolution NMR of Solids*.) Here we discuss only those aspects of DNP spectroscopy that are relevant for comparison and contrast with the related techniques mentioned above.

In DNP spectroscopy the NMR signal is detected directly. The ESR transition is used only as a source for achieving enhanced nuclear polarization. Theoretically a maximum enhancement of the NMR signal of the order of ω_e/ω_n can be achieved, but in practice significantly lower values are

usually observed. Direct detection of the NMR signal has the advantage that the high resolution of NMR spectroscopy is maintained. At the same time, this excludes from detection those nuclei which have large hyperfine couplings. This is a result of the combination of low sensitivity and the large shift in transition frequencies. DNP spectroscopy has been applied most successfully in cases where the ESR spectrum consists of a narrow line which is easily saturated. Examples include studies of fossil fuels¹⁹ and polymer interfaces.^{20–22}

Paramagnetically coupled nuclei may be observed directly as hyperfine splittings in the ESR spectrum. Such splittings are often observed in ESR spectra of organic radical molecules in liquids (see *Electron–Nuclear Hyperfine Interactions*). However, if the spin dynamics are not in the fast motion limit, hyperfine splittings are generally not resolved because of inhomogeneous line broadening.

Two different general approaches are available for measuring the magnetic couplings of nuclei which are not resolved in the ESR spectra. One approach is ESEEM.^{23–26} In this technique both the allowed and the semiforbidden ESR transitions are coherently excited using two or more short, intense microwave pulses. The nuclear hyperfine and quadrupole interactions (in the case of nuclei with spin multiplicity $I \geq 1$) are observed as a periodic modulation of the envelope of the primary spin echo or stimulated echo intensity. Fourier transformation of this modulation pattern yields a spectrum of frequencies corresponding to the hyperfine (and quadrupolar for $I \geq 1$) frequencies.

One of the advantages of the ESEEM experiment is its high sensitivity, which is roughly comparable with that obtained in an ESR experiment. Furthermore, by selecting the appropriate microwave excitation frequency and applied magnetic field conditions, it is possible to measure the pure nuclear quadrupolar resonance frequencies for nuclei with $I \geq 1$.^{27,28} This is possible despite the fact that the experiment is performed at finite magnetic field and the only spin transitions that are excited are the ESR transitions. One limitation of this type of experiment is that nuclear modulation can only be observed if the hyperfine interaction has finite anisotropic coupling components. The second criterion for modulation to be observed is that the microwave pulses must be able to excite both allowed and semiforbidden ESR transitions. This places constraints on the nature of the hyperfine interaction which will yield observable modulation. The theory, techniques, and applications of ESEEM spectroscopy have been reviewed in several texts and review articles.^{23–27,29}

The second approach for measuring the magnetic couplings of nuclei which are not resolved in the ESR spectra is directly to excite both the NMR and ESR transitions with rf and microwave excitation. The first double resonance experiment of this type, known as an ‘electron–nuclear double resonance’, or simply ENDOR, experiment was reported by Feher in 1956.³⁰ The continuous wave (CW) ENDOR experiment is performed by applying a strong microwave field which is selected to irradiate continuously an EPR transition while simultaneously applying a strong rf field. The rf field is swept through the range of frequencies that encompass the NMR spectrum while continuously observing the intensity of the EPR transition. The intensity of the latter changes whenever the rf frequency matches an NMR transition frequency. The intensity of the EPR transition plotted as a function of the rf frequency generates the ENDOR spectrum. Thus, the

ENDOR spectrum is a spectrum of the NMR transitions detected indirectly via the EPR transition. This is in contrast to the ESEEM experiment where the nuclear spin flip is a consequence of exciting a semiforbidden ESR transition. As a result, anisotropic hyperfine interactions are not necessary to observe hyperfine frequencies in the ENDOR experiment.

The ENDOR technique and applications have been documented in several texts and review articles.^{1,8,9,31–36} In the case of one electron coupled to a spin- $\frac{1}{2}$ nucleus, and considering for simplicity that the hyperfine interaction is isotropic, the ENDOR spectrum comprises two transitions corresponding to one NMR transition for each of the two electron spin states. There exists a one-to-one correspondence between the number of coupled inequivalent nuclei and the number of ENDOR transitions observed. This can be contrasted to the number of transitions observed in the EPR spectrum where the number of transitions observed is a multiplicative function of the number of inequivalent nuclei coupled to the unpaired electron spin. The reduced number of transitions results in spectral simplification and, consequently, in enhanced spectral resolution.

While the success of the CW ENDOR experiment has been well documented, certain inherent problems in the technique have also limited its applicability. One well-documented limitation of the CW ENDOR experiment is the constraints on the relationship between NMR and ESR relaxation rates that must be satisfied in order to observe an ENDOR signal.^{31,32,37–41} These constraints are changed (although not removed) with pulsed excitation techniques. This was recognized by W. B. Mims who reported the first pulsed ENDOR experiment in 1965, roughly a decade after Feher’s initial report of the CW ENDOR experiment. Since then the advantages and applications of employing pulsed excitation techniques for both the ESR and NMR transitions have been demonstrated in publications from several laboratories.^{37,38,41–46}

A second significant advantage of employing pulsed excitation techniques for both the ESR and NMR transitions is the potential for extending the type of experiments which can be performed. This is in many respects analogous to the extension of the experimental capabilities which become possible using pulsed excitation techniques in NMR spectroscopy. There are, however, distinct differences that must be kept in mind when using the analogy to pulsed NMR. These will be discussed in more detail in the next section. Furthermore, since multiple irradiation frequencies may be used to excite both the NMR and EPR transitions, the modern combined pulsed NMR and pulsed EPR experiments will be referred to as ‘pulsed electron NMR’ (PE NMR) spectroscopy. In this article, we describe the basic principles of these techniques, their implementation, including the pulse schemes and specific examples of experimental techniques, and illustrate the type of information that can be derived with examples in selected applications.

2 BASIC PRINCIPLES

In this section the magnetic interactions that determine the frequencies and amplitudes in pulsed ENDOR spectra are briefly reviewed. More comprehensive treatments can be found in several texts.^{2,6,31,32,47,48} The analysis of the pulsed ENDOR spectrum provides the starting point for understanding the extensions of the basic pulsed ENDOR technique. After

the properties of the pulsed ENDOR spectrum have been presented, the general approach for the PE NMR techniques will be introduced. This is followed by specific experimental techniques with examples of applications.

2.1 Nuclear Spin Interactions and the Spectrum

2.1.1 Transition Frequencies

For spin- $\frac{1}{2}$ nuclei, the NMR spectrum of the paramagnetically coupled nuclei is dominated by the local magnetic field generated by the unpaired electron spin and by the applied magnetic field. The magnitude and orientation of this local field depends on whether the electron spin is aligned along or opposed to the direction of the external magnetic field. The effect of the combined local field and applied field on the nuclear spin is described by the nuclear spin Hamiltonian (expressed in units of frequency)

$$\hat{\mathcal{H}}_n = \sum_{i=1}^3 (\hat{\mathbf{S}}' \cdot \mathbf{A} - g_n \beta_n B_0 b_i) \hat{I}_i \quad (1)$$

where the subscript $i = 1, 2, 3$ on $\hat{I}_i$ refers to the x, y, z components of the nuclear spin operator $\hat{\mathbf{I}}$. The prime on the electron spin operator $\hat{\mathbf{S}}'$ indicates that a coordinate system is selected in which the $\mathbf{g}$ tensor is diagonal. The b_i are the unit vectors of the applied magnetic field expressed in spherical polar coordinates:

$$(b_1, b_2, b_3) = (\cos \phi \sin \theta, \sin \phi \sin \theta, \cos \phi) \quad (2)$$

In most pulsed EPR experiments, particularly on transition metal ions, the microwave pulses excite only a small region of the spectrum centered about the magnetic field for resonance. This magnetic field position selects a subset of molecular orientations defined by the resonance condition, $h\nu = g\beta B_0$, where the orientation dependence of the electronic g factor is expressed by

$$g(\theta, \phi) = \left[\sum_{i=1}^3 (g_i b_i)^2 \right]^{1/2} \quad (3)$$

The number of molecular orientations which contribute to the ENDOR spectrum is minimum for values of (θ, ϕ) that correspond to the principal axes of the $\mathbf{g}$ tensor. This phenomenon is referred to as g -factor orientation selectivity.⁴⁹ Since a lower number of molecular orientations contribute, higher spectral resolution can be observed in ENDOR spectra recorded at magnetic field values corresponding to those values of (θ, ϕ) which correspond to these principal axes.

The local field is described by the term $\hat{\mathbf{S}}' \cdot \mathbf{A}$, where $\mathbf{A}$ is the hyperfine interaction tensor. The magnitude of the local field depends on the distance between the electron and the nucleus and on the nature of the chemical bonding that pertains to the electron and nucleus, i.e. on the electronic state in which the electron resides. The distance separating the electron and nucleus determines a classical dipolar interaction. Since the gyromagnetic ratio of the electron is very large, this

local magnetic field can be very large. The classical dipolar field will only provide a valid description of the distance between the electron and nucleus if the electron can be treated as a point dipole. Contributions to the hyperfine anisotropy also depend on the nature of the electronic wavefunction. The latter also determines whether the nucleus has a finite unpaired electron spin density at the nucleus. A finite unpaired spin density at the nucleus can only occur if the molecular orbital that describes the unpaired electron has some atomic s-orbital contribution in the wavefunction. The nonclassical contribution to the hyperfine anisotropy is sometimes referred to as 'pseudodipolar coupling'.

The orientation dependence of the local field can be expressed by an orientation-dependent hyperfine coupling $A(\theta, \phi)$. The NMR transition frequencies are then given by

$$\nu_{\pm} = \nu_n \pm \frac{1}{2} |A(\theta, \phi)| \quad (4a)$$

$$\nu_{\pm} = \frac{1}{2} |A(\theta, \phi)| \pm \nu_n \quad (4b)$$

where the first expression applies if $2\nu_n > |A|$ and the second expression applies if $2\nu_n < |A|$, while in both cases it is assumed that $I = \frac{1}{2}$.

The two limiting expressions [equations (4a) and (4b)] for the NMR frequencies are a recognition of the fact that the local magnetic field described by the hyperfine interaction can be comparable to or larger than the applied magnetic field. This is especially the case at the low applied field strengths, typically 0.35 T, at which many ENDOR and PE NMR experiments are performed. If the local field is greater than the applied field, then the local field is the dominant term that defines the nuclear quantization axis and the applied field is a perturbation. In either case, equations (4a) and (4b) indicate that for a nucleus with $I = \frac{1}{2}$, two NMR transitions will be observed in the ENDOR spectrum, with one transition originating from each of the two electron spin manifolds defined by the eigenvalue, $m_{S'}$, of $\hat{\mathbf{S}}'$. These NMR transitions will either be centered on the nuclear Larmor frequency if $2\nu_n > |A|$ or on one-half of the hyperfine coupling if $2\nu_n < |A|$.

In the case of organic radicals, the anisotropy of the g factor can be ignored in the first order analysis of the paramagnetically shifted NMR transitions. The NMR transition frequencies $\nu_{\pm}$ are then given by⁵⁰

$$\begin{aligned} \nu_{\pm} = & [(S_z A_{xx} - \nu_n)^2 \sin^2 \theta \cos^2 \phi \\ & + (S_z A_{yy} - \nu_n)^2 \sin^2 \theta \sin^2 \phi \\ & + (S_z A_{zz} - \nu_n)^2 \cos^2 \theta]^{1/2} \end{aligned} \quad (5)$$

where θ and ϕ are the spherical polar angles relating the applied static field $\mathbf{H}_0$ to the principal axis of the hyperfine tensor (A_{xx}, A_{yy}, A_{zz}). Equation (5) assumes that the high-field approximation is valid where the electron and nuclear spin operators $\hat{\mathbf{S}}$ and $\hat{\mathbf{I}}$ are completely decoupled from the molecular framework and quantized along the applied magnetic field direction. An energy level structure corresponding to an arbitrary selected set of (θ, ϕ) values is shown in Figure 1.

In general, the g factor for the electron will not be isotropic as assumed in the expressions described by equations (4a), (4b) and (5). Anisotropy of the electron g factor is usually

significant in ESR spectra of transition metal ions.^{6,7} If the g factor is anisotropic, the NMR frequencies and lineshape will depend on the magnetic field position and microwave frequency selected.^{6,48,51,52} In a noncrystalline solid, a single pair of NMR transitions will only be observed if the principal axes of the $\mathbf{g}$ and $\mathbf{A}$ matrices are collinear. Otherwise a powder pattern lineshape will be observed because of the angular dependence of the $\mathbf{g}$ and $\mathbf{A}$ matrices.

The NMR frequencies described in equation (5) do not account for the second-order frequency shifts of the ENDOR lines observed for large hyperfine couplings. Since these second-order frequency shifts are proportional to $A^2/4\nu_e$, they can usually be ignored under most experimental conditions. However, even for relatively small hyperfine coupling values, these second-order effects, arising from the spin Hamiltonian terms $\hat{S}_x\hat{I}_x$ and $\hat{S}_y\hat{I}_y$ must be included to calculate correct wave functions that reproduce the rf frequency dependence of the ENDOR amplitudes. These spin coupling terms lead to an enhancement, known as the ‘hyperfine enhancement’, of the rf field seen by the nucleus. Note that the enhancement can also be negative, i.e. a decrease in the rf field at the nucleus, depending on the eigenvalue m'_S of $\hat{S}'$.

The simple four-level system with isotropic hyperfine coupling described by the spin Hamiltonian:

$$h^{-1}\hat{\mathcal{H}}_0 = \nu_e\hat{S}_z - \nu_n\hat{I}_z + a\hat{S}_z\hat{I}_z \quad (6)$$

is usually adequate for describing the basic concepts for the sublevel polarization transfer experiments as well as several other PE NMR experiments described later in this article. In the high temperature limit, i.e. $g_e\beta_e B_0/kT \ll 1$, the spin eigenvalues, $h^{-1}E_0(M_S, M_I)$, are given by:

$$h^{-1}E_0(M_S, M_I) = \nu_e M_S - \nu_n M_I + a M_S M_I \quad (7)$$

The energy levels in Figure 1 also describe these eigenstates which arise from the coupling of an $S = I = \frac{1}{2}$ system with isotropic hyperfine coupling. With this level of simplification it is possible to gain considerable insight into the spin dynamics of PE NMR experiments using the spin operator formalism⁴² frequently used in NMR spectroscopy.⁵³

Figure 1 Energy level structure corresponding to the spin Hamiltonian of a four-level system. EPR, ENDOR, and relaxation transitions are identified

In the literature on pulsed ENDOR and PE NMR spectroscopy, the hyperfine splitting of the electron spin eigenstates are referred to as ‘hyperfine sublevels’ or simply as ‘sublevels’. The EPR, NMR, and spin relaxation transitions relevant in the discussion of the ENDOR experiment are identified in Figure 1. The ENDOR transitions indicated in the figure are NMR transitions detected indirectly by the ESR transition. The electron and nuclear relaxation transition probabilities W_e and W_n correspond to effective T_{1e}^{-1} and T_{1n}^{-1} rates; these are also identified in Figure 1. In the analysis of signal amplitudes in the CW ENDOR experiment, the effective rates are the intrinsic rates enhanced by the application of the microwave or rf excitation fields.

If the nuclear spin multiplicity $I \geq 1$, the quadrupolar interaction will result in additional splittings of the hyperfine sublevels. The quadrupolar interaction is described by adding the nuclear self-coupling term, $\hat{\mathbf{I}} \cdot \mathbf{P} \cdot \hat{\mathbf{I}}$ to the spin Hamiltonians of either equation (1) or equation (6). If the principal axes of the $\mathbf{g} \cdot \mathbf{A} \cdot \mathbf{P}$ are collinear and the magnetic field $\mathbf{B}_0$ is oriented parallel to one of these principal axes, the first-order ENDOR frequencies are given by^{2,6,48}

$$\nu_{\text{ENDOR}} = \left| \frac{A_i}{2} \pm \nu_n \pm \frac{3}{2} |P_i| (2m_i + 1) \right| \quad (8)$$

where A_i and P_i denote the principal values of the $\mathbf{A}$ and $\mathbf{P}$ tensors along the i axis. The nuclear transitions in equation (8) are assumed to increase in the nuclear spin quantum number, i.e. $m_I \rightarrow m_I + 1$. It has also been assumed that $(|A| > 2\nu_n > 3|P_i|)$. The principal values of the quadrupolar tensor $\mathbf{P}$ are defined as $|P_{zz}| > |P_{yy}| > |P_{xx}|$. These principal values are related to the magnitude of the quadrupolar coupling constant χ and asymmetry parameter η by

$$\chi = 2I(2I - 1)P_{zz} \quad (9a)$$

$$\eta = \frac{P_{xx} - P_{yy}}{P_{zz}} \quad (9b)$$

According to equation (8), four ENDOR transitions are expected for a nucleus with $I = 1$. However, not all ENDOR transitions may be observed when exciting an ESR transition at a given magnetic field value, since it is possible that each m_I state may be selectively excited. For example, a two-line ENDOR spectrum will be observed if the ESR transition connects the $m_I = 1$ to $m_I = 1$ sublevels of the $m_S = +\frac{1}{2}$ and $m_S = -\frac{1}{2}$ electron spin manifolds.

2.1.2 ENDOR Amplitudes

ENDOR signal amplitudes are proportional to the change in the EPR signal intensity, ΔE , induced by an NMR transition. Since the EPR signal intensity E is proportional to the electron spin susceptibility χ_e , a relative ENDOR susceptibility can be defined by

$$\frac{\Delta \chi_e}{\chi_e} = \frac{\Delta E}{E} \quad (10)$$

The transition frequencies and amplitudes that are described by the time-independent terms in the spin Hamiltonian are independent of the method of exciting and detecting the transitions. However, the dynamic terms of the total spin Hamiltonian that describe the spin system have different effects on the amplitudes in the CW and pulsed experiment. In the CW experiment, the ENDOR signal amplitude depends on the rate at which the ESR and NMR transitions are excited by the applied microwave and rf magnetic fields compared with the rate of intrinsic relaxation pathways that will compete to restore the spin system to thermal equilibrium. Once the spin eigenstates and relaxation rates that connect the eigenstates have been defined, coupled rate equations can be used to model the ENDOR signal amplitude. In contrast, the pulsed ENDOR or ENMR experiment is performed on a timescale which is short compared with the intrinsic spin relaxation rates. The amplitudes can therefore be analyzed without resorting to coupled rate equations.

In the CW experiment, the interplay between the transition intensity induced by the applied magnetic fields and the intrinsic spin relaxation rates is further complicated by the effect of the hyperfine enhancement on the ENDOR amplitudes.^{31,32,50,54} For intense rf fields, the ENDOR amplitudes can be independent of the rf frequency. For very weak rf fields, the ENDOR amplitudes increase with the square of the rf frequency. For intermediate values, the ENDOR amplitudes can be a complex function of the transition moments and relaxation parameters, especially since both the transition moments and the relaxation rates can be orientation dependent.

In pulsed ENDOR experiments, the analysis of the hyperfine enhancement and the effects of the spin relaxation on the ENDOR amplitudes is less complex. The pulsed ENDOR experiment is usually performed on a timescale which is short compared with the electron, nuclear, and the electron–nucleus cross-relaxation rates. In this case the relaxation rates do not influence the relative ENDOR amplitudes. The loss of electron spin polarization by T_{1e} processes during the mixing period (described in Section 2.2) results in a uniform decrease in the signal amplitudes, $\Delta\chi_e/\chi_e$, across the ENDOR spectrum. The hyperfine enhancement of the NMR transition moment is then simply observed as a change in the sublevel nutation angle as a function of rf frequency. The sublevel nutation angle θ_R is given by $\theta_R = \gamma_n \epsilon B_2 t_{rf}$, where ϵ is the hyperfine enhancement factor. If the hyperfine interaction is isotropic, the hyperfine enhancement factor is given by $\epsilon = |1 + m_s a/\nu_n|$. The hyperfine enhancement can be observed directly in EPR detected sublevel transient nutation experiments.^{43,55}

As described in the next section, the pulsed ENDOR experiment can be divided into pulse periods. The ENDOR amplitude is a function of the microwave pulses in the preparation period and detection period as well as of the nutation angle of the sublevel polarization in the mixing period. The latter can be expressed by

$$EA(\nu_{rf}) = \frac{1}{2}(1 - \cos(\theta_{R\pm})) \quad (11)$$

In the limit of small nutation angles, the cosine term can be expanded in a power series:

$$EA(\nu_{rf}) \approx \frac{(\theta_{R\pm})^2}{4} = \frac{(m_s A)^2}{(2\nu_n)^2} = \frac{(m_s)^2}{(2\nu_n)^2} (\nu_{\pm} - \nu_n)^2 \quad (12)$$

Equation (12) explicitly indicates that the Fermi golden rule result for the rf frequency dependence of the transition probability is obtained in the limit of small nutation angle. If the nutation angle is adjusted to correspond to a π pulse at each ENDOR frequency, the ENDOR amplitudes should be independent of the hyperfine enhancement factor. It is straightforward, although time consuming, to measure the sublevel nutation frequency at each ENDOR frequency in the ENDOR spectrum for a quantitative analysis of the ENDOR amplitudes. Additional contributions to the ENDOR amplitudes arise from the effect of hyperfine contrast selectivity in the preparation period and from possible electron–nucleus coherence effects in the detection period.^{37,38} These effects are discussed in more detail in Section 3. Contributions originating from the hyperfine anisotropy^{6,48} and g -factor orientation selectivity^{6,48} will also affect the amplitudes in both the CW and pulsed ENDOR experiments.

2.2 Pulse Schemes

Many of the PE NMR experimental techniques can be understood by analogy to heteronuclear NMR experiments. However, in making this comparison between PE NMR and heteronuclear NMR experiments, some important differences must be recognized. These originate from the fundamental properties of the unpaired electron compared with a nucleus. The two most significant differences are the γ values of the electron and nucleus and the differences between the nature of the wave functions that describe the electron and the nucleus.

The larger γ for the electron compared with any nucleus has two important consequences. The first is the practical consequence for the type of instrumentation required for PE NMR experiments compared with heteronuclear NMR experiments. The heteronuclear NMR experiment requires a transmitter, probe, and receiver capable of handling two (or more) different rf frequencies. In contrast, for the double resonance experiment between the electron and nucleus, the hardware must be capable of handling both rf and microwave frequency components.

A second consequence of the larger γ of the electron is that the local magnetic field generated by the electron is much larger than is generated by any nucleus. This has several consequences on the properties of the spectra observed for nuclei that are coupled to this local field and also has implications on the types of experiments which can be performed. In most cases, PE NMR experiments must be analyzed within the so-called ‘soft pulse limit’, i.e. the bandwidth of the excitation pulses for both the ESR and NMR transitions are much smaller than the spectral bandwidth. In other words, both the ESR and NMR pulses are generally selective excitation pulses. The broad linewidths also exclude certain techniques such as cross polarization in the rotating frame and magic angle spinning which have had such an important impact on NMR of solids from being directly adapted to PE NMR experiments.

The second important difference to bear in mind when comparing PE NMR spectroscopy with pulsed heteronuclear NMR is the difference in the nature of the total wavefunction associated with the electron compared with the nucleus. The electron is generally in an eigenstate, such as an atomic or

molecular orbital, which has a much greater spatial extent than the localized eigenstate which describes the nucleus. This has the consequence that the electron spin is delocalized so that the electron is generally coupled to many more nuclei than would be the case if the electron were represented by a point dipole. The delocalization of the electron spin density in molecular orbitals that have well defined spatial extents can also contribute large anisotropic components to the local (i.e. hyperfine) field. The anisotropy of the hyperfine interaction also assures that the quantization axis for the nucleus does not point in the same direction in the two electron spin eigenstates. This anisotropy in the hyperfine interaction is therefore responsible for the broad spectral widths observed for the NMR transitions and also affects the transitions which are observed, since formally forbidden transitions become ‘semiforbidden’ transitions.

Another consequence of the nature of the electronic states that host the unpaired electron is that spin coupling mechanisms such as the spin–orbit coupling are effective in broadening the ESR linewidth and in enhancing the spin relaxation rate. Both the broad lines and the shorter relaxation times have implications on the types of PE NMR experiments that can be performed.

The pulse sequences employed in PE NMR experiments can be conveniently divided into pulse periods in direct analogy to NMR spectroscopy. With the above-mentioned caveats in mind, the pulse periods can be analyzed by analogy to a pulsed heteronuclear NMR solids experiment within the soft pulse limit, wherein selective excitation is considered in the analysis. The most basic experiment consists of a preparation, mixing, and detection period. The purpose of the preparation period is to create an initial state perturbed from the equilibrium spin polarization established by the conditions of the temperature and external field (as well as by the level structure of the electron–nucleus coupled spin system). In all PE NMR experiments reported to date, one or two microwave pulses are applied to excite ESR transitions in the preparation period.

Two basically different types of PE NMR experiments will be performed depending on whether the microwave preparation pulses have created sublevel nuclear spin polarization or electron spin coherence at the end of the preparation period. The former are the starting points for ESR detected sublevel polarization transfer experiments and for ESR detected nuclear coherence experiments. The latter is the starting point for coherence transfer ENDOR experiments. In this experiment, a single microwave pulse, ideally a $\pi/2$ pulse, creates electron spin coherence in the preparation period.

In the mixing period, one or more rf pulses are applied to manipulate the sublevel polarization or sublevel coherence. The nature of the perturbation determines the type of experiment performed. The mixing period may include an evolution period, again depending on the type of experiment performed. If sublevel nuclear coherence has been created and is to be indirectly observed via the ESR transition intensity, the mixing period must end with a $\pi/2$ rf pulse that converts the sublevel coherence to sublevel polarization.

In the detection period one or more microwave pulses are applied to create electron spin coherence which is detected in the PE NMR experiment. The electron spin transverse magnetization provides a readout of the electron–nucleus longitudinal order. The transverse magnetization can be

detected by a primary spin echo,⁵⁶ a stimulated echo,⁵⁷ or as a free induction signal.⁵⁸ It is also possible to use CW irradiation to detect the transverse electron magnetization⁴² or to detect the longitudinal electron magnetization directly.²⁹

3 EXPERIMENTAL TECHNIQUES WITH SELECTED APPLICATIONS

3.1 ESR Detected Sublevel Polarization Transfer

It is possible to envisage many pulse sequences which create sublevel nuclear spin polarization. The most common methods, shown in Figure 2, are a single microwave pulse which selectively excites one ESR transition or two microwave pulses. The former was first proposed by Davies⁵⁶ and is the starting point for what has become known as the Davies ENDOR experiment. The latter was first proposed by Mims⁵⁷ and is the preparation pulse sequence for the experiment now known as Mims ENDOR.

Referring to Figure 3, the selective excitation of one of the two allowed ESR transitions converts the electron spin polarization, represented by the boxes, into electron–nucleus two-spin longitudinal order. The spin polarization from the nuclear Zeeman and hyperfine interactions is negligible compared with the electron spin polarization and can be ignored. The two spin order refers to the fact that the nuclear spins in both NMR transitions are polarized.

Two spin electron–nucleus longitudinal order can also be created using two selective microwave pulses or two nonselective microwave excitation pulses if an evolution time separates the two pulses.⁴² Sublevel polarization is created from the transverse components of the magnetization that evolves following the first pulse in the local field of the hyperfine interaction. The second pulse converts the transverse magnetization to two-spin longitudinal order. This suggests that the two pulses should be $\pi/2$ pulses for maximum efficiency in creating sublevel polarization. After the second

Figure 2 Davies ENDOR (a) and Mims ENDOR (b) pulse sequences

Figure 3 The transfer of spin polarization during the preparation (a), mixing (b) and detection (c) periods of the Davies ENDOR sequence for the four level system shown in Figure 1

pulse, the net sublevel polarization is approximately $\sin(a\tau/2) \sin(\Omega_S\tau)$, where a is the hyperfine coupling in equation (6) and Ω_S is a resonance offset. Note that no sublevel polarization exists for values $a\tau/2 = n\pi$, where n is an integer. These are known as blind spots in the Mims ENDOR experiment.

For an ESR lineshape which is inhomogeneously broadened, the sublevel polarization created by the microwave pulses in the preparation period burn a hole into the envelope of the ESR absorption lineshape as shown in Figure 4(a). The width of the hole is determined by the excitation bandwidth of the preparation pulse. In the case of two pulse excitation, a serrated pattern of magnetization is superimposed on the hole, as shown in Figure 4(b).

3.1.1 Davies and Mims ENDOR

The pulse sequences for the two most commonly used experiments for the ESR detection of sublevel polarization transfer are shown in Figure 2. The hole-burning effect created by the preparation pulses on an inhomogeneously broadened ESR absorption envelope is shown in Figure 4. The effect of a selective ESR excitation on the electron spin polarization in a four level system described by equation (7) is shown in Figure 3(a). The electron spin polarization associated with these two energy levels will be inverted if the selective microwave pulse is a π pulse. Note that the sublevel longitudinal polarization of both the upper and lower NMR sublevels are not at equilibrium at the end of the preparation period.

In the next step of the pulse sequence, an rf pulse transfers and thereby ‘mixes’ the electron spin polarization between the sublevels. This is shown in Figure 3(b) for an rf pulse on resonance with the upper sublevel. In the hole-burning picture shown in Figure 4, the sublevel polarization transfer corresponds to the transfer of polarization from within the hole to a frequency offset by the value of the hyperfine coupling. This sublevel polarization transfer occurs at frequencies corresponding to the NMR frequency shifted by the hyperfine interaction (see Section 2.1.1).

The sublevel polarization transfer could, in principle, be detected directly as an NMR signal. Indeed, this would correspond to a pulsed DNP experiment. Note, however, that the sublevel polarization transfer has also changed the electron longitudinal polarization of the two ESR transitions. The sublevel polarization transfer can therefore be detected by

Figure 4 EPR spectra of an inhomogeneously broadened line after the preparation period in the Davies ENDOR (a) and Mims ENDOR (b) pulse sequences. (Reproduced by permission of Academic Press from H. Thomann and M. Bernardo, in ‘Methods in Enzymology’, eds. J. F. Riordan and B. L. Vallee, 1993, Vol. 227, Chap. 6)

measuring the change in the ESR transition intensity. This can be accomplished using a variety of techniques, as discussed in Section 2.2. In the Davies and Mims ENDOR pulse sequences the change in electron longitudinal polarization is detected by observing the change in intensity of a primary or stimulated spin echo. This electron spin coherence is indicated by the double arrow in Figure 3(c).

The spectrum of NMR transition frequencies shifted by the hyperfine coupling, i.e. the ENDOR spectrum, usually far exceeds the excitation bandwidth of the rf pulses. The complete spectrum must therefore be recorded by incrementing stepwise the rf frequency on successive iterations of the pulse sequences shown in Figure 2. The limit of resolution in the spectrum is determined by the excitation bandwidth of the rf pulse.

The Davies ENDOR spectrum of a single crystal of malonic acid which has been irradiated by X-rays to generate carbon π radicals⁵⁹ is shown in Figure 5. The transitions at approximately 5 and 30 MHz are the two sublevel transitions associated with the α proton of the CH fragment of the $\cdot\text{CH}(\text{COOH})_2$ radical molecule. The other proton lines originate from the carboxylic protons, from coupling to protons on neighboring malonic molecules, and from overlapping ESR signals from different malonic acid radical molecules.⁵⁹ The increase in spectral resolution obtained by decreasing the excitation bandwidth of the rf mixing pulse is shown in the inset of the figure.

The relative amplitudes of the ENDOR transitions are determined by the spin Hamiltonian (as discussed in

Figure 5 Davies ENDOR spectrum of an X-ray irradiated crystal of malonic acid with rf pulse widths of 5 μ s (a) and 10 μ s (b). (Reproduced by permission of the American Chemical Society from H. Thomann and M. Bernardo, in 'Advances in Chemistry Series 229: Magnetic Resonance of Carbonaceous Solids', eds. R. E. Botto and Y. Sanada, Washington, DC, 1993, Chap. 4)

Section 2.1.2) but also by the excitation bandwidth, Δ_p of the preparation pulse. In order for a sublevel polarization transfer signal to be detected indirectly using the Davies ENDOR pulse sequence [Figure 2(a)], the condition that $\Delta_p > a$, where a is the hyperfine coupling, must be satisfied.⁵⁶ If $\Delta_p > a$, the transfer of polarization remains within the hole burned into the absorption envelope. In this case the change in electron polarization is reduced, resulting in a weaker ENDOR signal. This relationship between Δ_p and a has been referred to as 'hyperfine contrast selectivity',^{37–39} as a 'spin alignment hole',⁴¹ and as a 'self-ELDOR effect'.⁴² The relationship between Δ_p and a can be used to eliminate or reduce the overlap of ENDOR signals originating from nuclei with different hyperfine couplings.^{37–39,60}

Davies ENDOR spectra on a blue copper protein, stellacyanin,⁶¹ will serve to illustrate the application of pulsed ENDOR (and PE NMR) spectroscopy. Transition metal ions and ion clusters are found at the active site for electron transfer in metalloproteins and at the active site for substrate conversion in metalloenzymes. The electron spin echo detected ESR (ED ESR) absorption envelope recorded by plotting the intensity of the primary electron spin echo as a function of magnetic field is shown in the inset of Figure 9. A spectroscopic model for the ligand coordination structure of the Cu^{2+} ion for the high-pH form of the protein is shown in Figure 6. The hyperfine coupling frequencies for each nucleus on the copper ligands are indicated in Figure 6. The NMR transitions for nuclei in the primary ligand coordination

Thomann and M. Bernardo, in 'Methods in Enzymology', eds. J. F. Riordan and B. L. Vallee, London, 1993, Vol. 227, Chap. 6)

Figure 7 Davies ENDOR spectra of stellacyanin using microwave inversion and detection pulse widths t_{mw} of 0.40, 0.20, 0.40 μ s (a) and 0.04, 0.02, 0.04 μ s (b). (Reproduced by permission of Academic Press from H. Thomann and M. Bernardo, in 'Methods in Enzymology', eds. J. F. Riordan and B. L. Vallee, 1993, London, Vol. 227, Chap. 6)

structure of the Cu^{2+} ion would be difficult to measure by any other spectroscopic technique.

The hyperfine contrast selectivity mechanism for eliminating the overlap of ENDOR lines is illustrated in Figure 7, where two Davies ENDOR spectra of stellacyanin⁶¹ are shown. When a preparation pulse with narrow excitation bandwidth is used [Figure 7(a)], the proton ENDOR lines which have small hyperfine coupling values that originate from protons on the two imidazole ligands overlap the nitrogen ENDOR lines, particularly the nitrogen line centered at roughly 8 MHz. When a larger excitation bandwidth is used [Figure 7(b)] the amplitudes for these proton ENDOR lines are significantly attenuated. The 1 : 2 relative intensities of the two ^{14}N ENDOR lines centered at 8 and 18 MHz in Figure 7(b) are in agreement with the expected intensity difference due to the hyperfine enhancement factor.^{37,38}

The proton ENDOR signals from protons with small hyperfine couplings can also be observed using preparation pulses with large excitation bandwidths with the Mims ENDOR pulse sequence. A comparison of the Davies and Mims ENDOR spectra for the stellacyanin protein is shown in Figure 8. The arrows in the Mims ENDOR spectrum indicate the positions of the 'blind spots' where no ENDOR signal is observed. The position of these blind spots in the spectrum

Figure 8 Comparison of the Davies and Mims ENDOR spectra for the stellacyanin protein. (Reproduced by permission of Academic Press from H. Thomann and M. Bernardo, in 'Methods in Enzymology', eds. J. F. Riordan and B. L. Vallee, London, 1993, Vol. 227, Chap. 6)

can be selected by the value of τ chosen in the Mims ENDOR pulse sequence. Note that the ENDOR signal for the protons with small hyperfine couplings is significantly enhanced in the Mims ENDOR spectrum. This is a consequence of the fact that a larger fraction of the electron magnetization can be sampled without suppressing the ENDOR signals from the nuclei with small hyperfine couplings.

An example of the advantage of the increased sensitivity achieved by the indirect detection scheme of the pulsed ENDOR experiment is shown in Figure 9, where the ENDOR signals from the central metal Cu^{2+} ion as well as those from all the (NMR active) ligand nuclei on the metal ligands are observed. The position in the ED ESR spectrum at which this Davies ENDOR spectrum was recorded is shown in the inset of the figure. Although the hyperfine splitting of the Cu^{2+} ion can be observed at the high-field end of the ESR spectrum, the hyperfine splittings are not resolved in the low-field region of

Figure 9 Davies ENDOR spectra of stellacyanin showing the Cu, N, and H resonances. Inset shows the position in the ED ESR spectra where the ENDOR spectra was recorded. (Reproduced by permission of Plenum Press from H. Thomann and M. Bernardo, in 'Biological Magnetic Resonance', eds. L. J. Berliner and J. Reuben, New York, 1993, Vol. 13, Chap. 7)

the ESR spectrum. Note also that the pulsed ENDOR spectrum reveals the quadrupolar splitting of the Cu^{2+} nucleus. It is not possible to measure these quadrupolar interactions in the ESR spectrum.

3.1.2 Transient Nuclear Nutations

The sublevel nuclear transient nutations can be detected indirectly with the pulse sequences in Figure 2 by incrementing stepwise the rf pulse length on successive pulse sequence iterations. An example is shown for the malonic acid radical in Figure 10. The effect of the time dependence of the signal from the electron spin-lattice relaxation during the mixing time can be eliminated by choosing a fixed, long mixing time before detection or by subtracting the signal recorded without the rf pulse applied (or with the rf frequency set to an off-resonance position in the ENDOR spectrum). The electron spin echo amplitude in the detection period oscillates with a periodicity proportional to $\cos \theta_2$ where θ_2 is the sublevel nutation angle (see Section 2.1.2). These oscillations are sometimes referred to as Rabi oscillations. The influence of the hyperfine enhancement factor on the nutation angle is evident in Figure 10.

The sublevel nutation experiment provides a method for setting the rf mixing pulse conditions to the selected nutation angle. For ESR detected sublevel polarization transfer experiments, the optimum pulse is a π pulse. For the ESR detection of sublevel coherence, the rf mixing pulse would be set for a $\pi/2$ pulse. For samples which are not single crystals and that exhibit hyperfine anisotropy, the Rabi oscillations are rapidly damped after the first period.^{37,38} Consequently, the effect on the ENDOR amplitudes due to the hyperfine enhancement can be reduced by selecting a long rf pulse length. However, this produces power broadened lines, and therefore a lower resolution in the spectrum. When two or more magnetically equivalent nuclei are coupled to the electron, harmonics may be observed in the sublevel nutation pattern.⁴² An example is shown in Figure 11. Analysis of these

harmonics provides a method for determining the number of equivalent nuclei coupled to the electron.

3.1.3 Optimized Davies and Mims ENDOR

The Davies or Mims ENDOR pulse sequences produce a maximum ENDOR enhancement of $\Delta\chi_e/\chi_e = 1$. A pulse scheme for theoretically increasing this efficiency to $\Delta\chi_e/\chi_e = 2$ has been proposed and demonstrated.⁴² This is accomplished by inserting a microwave π pulse and a second rf π pulse following the first rf π pulse in the mixing period. This pulse sequence is the pulsed analog of the Special TRIPLE resonance technique which was also introduced to improve the efficiency in the CW ENDOR experiment.^{34,62,63} In practice, the improvement in efficiency of the Davies or Mims ENDOR signal intensity is much smaller than theoretically possible, primarily because of pulse imperfections. Nevertheless, a gain in ENDOR enhancement is observed, as shown in the example given in Figure 12. Nonideal nutation angles due to pulse imperfections are particularly problematic for noncrystalline samples where the ENDOR lines are significantly overlapped.

3.1.4 Electron–Nucleus Coherence Effects

Electron–nucleus coherence effects can be observed in the Davies ENDOR experiment if the microwave pulses in the detection period excite both allowed and semiforbidden ESR transitions.^{38,37} These coherence effects generate a nuclear modulation on the envelope of the primary electron spin echo in the detection period analogous to the ESEEM experiment. An example of this phenomenon is shown in Figure 13 where two Davies ENDOR spectra for the blue copper protein,

Figure 12 Mims-ENDOR spectra (a) of Cu(II)-doped TGS single crystal around the proton transition at $\omega_p/2\pi = 10.15$ MHz and the optimized spectra obtained using the pulse sequence described in the text. (Reproduced by permission of Academic Press from C. Gemperle et al., *J. Magn. Reson.*, 1990, **87**, 502)

stellacyanin, are shown recorded for two different values of the spin echo delay time τ in the detection period. The values of τ used in the detection period are indicated on the echo envelope waveform shown in the inset. These coherence effects can have important consequences for the analysis of the ENDOR spectrum. Note that the relative amplitudes of the ENDOR intensities depend on the value of τ in the detection period. This effect can be used as a spectral editing technique.^{38,37}

3.1.5 Electron–Nucleus–Nucleus Triple Resonance

The Double ENDOR was originally introduced as a CW ENDOR technique to establish the connectivity of hyperfine sublevels and to determine the relative signs of the hyperfine interaction for nonequivalent nuclei.^{63,64} The pulsed implementation of the Double ENDOR experiment is shown in Figure 14.⁴¹ The experiment is analogous to the Davies ENDOR experiment, except that a second rf π pulse is inserted in the mixing period to irradiate a preselected ENDOR transition. The Double ENDOR difference spectrum, obtained from the difference between the ENDOR and Double ENDOR spectrum, identifies any changes in intensities of the ENDOR transitions induced by pumping at the second rf frequency. A peak in the Double ENDOR difference spectrum will only be

Figure 13 Davies ENDOR spectra of stellacyanin at the two pulse modulation minimum at $\tau = 0.40 \mu\text{s}$ (a) and at the maximum at $\tau = 0.51 \mu\text{s}$ (b). (Reproduced by permission of Academic Press from H. Thomann and M. Bernardo, in *Methods in Enzymology*, eds. J. F. Riordan and B. L. Vallee, London 1993, Vol. 227, Chap. 6)

observed if the two sublevels each have a level in common with the ESR transition.

An example of the pulsed Double ENDOR and Double ENDOR difference spectrum recorded for the radical in the conjugated conducting polymer, polyacetylene, is shown in Figure 15.⁴¹ The Double ENDOR difference spectra indicate that the unpaired electron is coupled to protons with both positive and negative hyperfine interactions. In this case, similar conclusions were obtained using the CW Double ENDOR experiment and the results were used to determine an electron–electron correlation energy using a Hartree–Fock molecular orbital calculation.⁶⁵ However, the CW Double ENDOR experiment was only successful over a restricted temperature range, which is not the case for the pulsed version of the experiment. The pulsed Double ENDOR experiment has also been applied to studies of the irradiated malonic acid radical molecule^{45, 43} and to studies of the coordination

structure of transition metal ions and metal clusters in metalloenzymes.³⁸

3.1.6 Electron–Nucleus–Electron Triple Resonance

Another variation of a pulsed triple resonance experiment is shown in Figure 16.^{38, 37} This experiment is related to the Davies ENDOR experiment, except that the frequency of the detection pulses are offset by a frequency Δ from the frequency of the preparation pulse. This is shown schematically in Figure 17 by the magnetic positions at which the preparation, indicated by B_p , and detection, indicated by B_d , irradiation pulses are applied within the ESR absorption envelope. Sublevel polarization transfer that connects the positions B_p and B_d must originate from rf driven sublevel NMR transitions. Polarization transfer by mechanisms other than rf driven nuclear spin flips, such as by spin diffusion, are ineffective because of the short time interval between the preparation and detection period. The value of Δ therefore preselects nuclei with the hyperfine coupling $A = \Delta$. For this reason, the ENDOR spectrum generated for $\Delta = A$ is referred to as a hyperfine selective (HS) ENDOR spectrum. An HS ENDOR spectrum can also be generated by jumping the applied magnetic field.⁴²

The HS ENDOR technique is illustrated in Figure 18. The Davies ENDOR spectra for the blue copper protein, stellacyanin, recorded for the native pH 7 form of the protein and for the high-pH (pH 11) perturbed blue form of the protein are shown in Figures 18(a) and 18(b), respectively. The spectra are identical except for the intensity of a transition at 21 MHz observed in the spectrum of the high-pH form. The assignment of this peak is facilitated using the HS ENDOR experiment, as

Figure 16 Pulsed electron–nucleus–electron triple resonance pulse sequence. (Reproduced by permission of Academic Press from H. Thomann and M. Bernardo, in ‘Methods in Enzymology’, eds. J. F. Riordan and B. L. Vallee, London 1993, Vol. 227, Chap. 6)

illustrated by the three HS ENDOR spectra recorded for values of $\Delta = 19, 42$, and 36 MHz, which are shown in Figures 18(c), 18(d) and 18(e) respectively.

3.2 EPR Detected Sublevel Nuclear Coherence

Sublevel coherence can be created by a $\pi/2$ rf pulse applied at the end of the preparation period. Once created, this sublevel coherence can be manipulated in analogy to many other solid state NMR experiments. Specific examples of these type of experiments are described in this section.

3.2.1 Nuclear Free Induction

The evolution of the sublevel coherence under free precession in the local field can be detected indirectly using the pulse sequence shown in Figure 19.^{41,43} The frequency of the rf pulses are set to excite a transition in the ENDOR spectrum. The sublevel coherence evolving during the evolution time t_1 is converted back to electron spin longitudinal polarization by a second rf $\pi/2$ pulse. The sublevel coherence signal at evolution time t_1 is then detected indirectly from the intensity

Figure 18 Davies ENDOR spectra of the native (pH 7) form (a) and the high-pH (pH 11) form (b) of stellacyanin. HS ENDOR spectra of the high pH form with $\Delta = 19.0$ (c), 42.0 (d), and 36 (e) MHz were used to assign the feature at 21 MHz to nitrogen. (Reproduced by permission of Academic Press from H. Thomann and M. Bernardo, in ‘Methods in Enzymology’, eds. J. F. Riordan and B. L. Vallee, London, 1993, Vol. 227, Chap. 6)

modulation of the primary electron spin echo in the detection period. The sublevel free induction signal is then detected point by point by incrementing t_1 on successive pulse sequence iterations. Both the in-phase and phase-quadrature sublevel free precession signals can be detected by phase shifting the relative phase of the two rf pulses by $\pi/2$. Additional phase cycling by π can be used to cancel the effects of electron spin–lattice magnetization recovery during the t_1 evolution period. The rf pulse excitation bandwidth is usually much smaller than the spectral spread of the ENDOR spectrum. In order to record the entire ENDOR spectrum, the pulse sequence shown in Figure 19 must be repeated with the rf frequency incremented on successive experiments. A spectral slice of the overall ENDOR spectrum, determined by the bandwidth of the rf excitation pulse, is recorded for each selected rf. The whole ENDOR spectrum is reconstructed by adding the slices of the limited spectral regions recorded in each experiment.

The ESR detected sublevel free precession experiment is illustrated in Figure 20. These data are collected for a crystal of irradiated malonic acid. In the Davies ENDOR spectrum, a transition that shows no evidence of fine structure is observed at 14.42 MHz. The in-phase and phase-quadrature sublevel free precession signals recorded using the pulse sequence in Figure 19 and the procedure described above are shown in Figure 20(a). The complex Fourier transform of these waveforms is shown in Figure 20(b). This spectrum indicates that the ENDOR line is composed of three overlapping

transitions which are not resolved in the Davies ENDOR spectrum.

3.2.2 Multiple Quantum Electron–Nucleus Coherence

The coupling of two or more nuclei with equivalent hyperfine couplings can be detected indirectly using the pulse sequences shown in Figure 21.^{41,66} The sublevel polarization can be created using either the inversion–recovery technique with primary spin echo detection (i.e. as in the Davies ENDOR pulse sequence) or by the two pulse excitation in the preparation period with a single pulse in the detection

Figure 21 Multiple quantum (MQ) ENDOR pulse sequences: Davies MQ ENDOR (a) and Mims MQ ENDOR (b). (Reproduced by permission of Laser Pages Publishing from H. Thomann and M. Bernardo, *Isr. J. Chem.*, 1992, **32**, 323)

period to create a stimulated echo (i.e. as in the Mims ENDOR pulse sequence). An n -quantum sublevel coherence is detected using the phase incrementation technique in analogy to the NMR experiment.^{53,67} An n -quantum coherence accumulates a phase $\theta_n = n\omega_{\text{ENDOR}}t_{\text{evol}}$ where t_{evol} is an evolution time and ω_{ENDOR} is the sublevel transition frequency.

In the present experiments the phase accumulation occurs during the nutation of the sublevel polarization so that $t_{\text{evol}} = t_{\text{p}}^{\text{rf}}$. This phase accumulation can be detected by incrementing the phase of the rf mixing pulse in the middle of the mixing period. Theoretically, the optimum ENDOR signal is obtained by applying two $\pi/2$ rf pulses. Each point on the plot of the phase interferogram is collected by incrementing the phase of the second rf pulse on successive pulse sequence iterations.

An example of a multiple quantum spectrum recorded using the pulse sequence in Figure 21(a) for the malonic acid radical molecule is shown in Figure 22.⁶⁶ Multiple quantum coherences up to $n = 3$ are observed for an ENDOR transition at 14.42 MHz recorded for the malonic acid radical molecule in a crystal at an arbitrary orientation. This is consistent with the three lines observed in the ESR detected sublevel FID spectra recorded under identical conditions [Figure 20(b)]. Multiple quantum spectra recorded for several evolution times for free precession are also shown in Figure 22. The oscillation for each order of coherence originates from the free precession of transverse sublevel magnetization in the presence of the local field.

3.2.3 Nuclear Spin Echoes

Hyperfine sublevel spin echoes can be created and detected indirectly by inserting a refocusing rf pulse in the evolution period of the mixing period for the pulse sequence shown in Figure 20. The pulse sequence for this indirect detection of sublevel spin echoes is shown in Figure 23.^{40,41} The first rf pulse in the mixing period creates sublevel coherence. This coherence evolves under free precession for time τ_n and is

Figure 22 Davies multiple quantum ENDOR spectra of the malonic acid radical for various evolution times. (Reproduced by permission of Laser Pages Publishing from H. Thomann and M. Bernardo, *Isr. J. Chem.*, 1992, **32**, 323)

Figure 23 Pulse sequence for EPR detection of sublevel spin echo. (Reproduced by permission of the American Chemical Society from H. Thomann and M. Bernardo, in 'Advances in Chemistry Series 229: Magnetic Resonance of Carbonaceous Solids', eds. R. E. Botto and Y. Sanada, Washington, DC, 1993, Chap. 4)

then refocused by the rf π pulse. The sublevel spin echo formed at time τ_n after the refocusing pulse can be detected by incrementing the time t_1 of the third rf mixing pulse. The third rf pulse transforms the sublevel coherence into two spin electron–nucleus longitudinal order. This is transformed to electron spin coherence for detection of the electron spin polarization by the microwave pulses in the detection period.

The sublevel echo can be detected point by point by incrementing the value of t_1 from $t_1 < \tau_n$ to $t_1 > \tau_n$ on successive pulse sequence iterations. In each pulse sequence iteration the sublevel coherence is detected by the change in intensity of the electron spin echo in the detection period. An example of sublevel spin echoes detected by this procedure for an X-ray irradiated malonic acid crystal are shown in the inset of Figure 24. The two sublevel spin echoes shown were recorded for τ_n values of 5 and 20 μ s.

The circles shown in the inset of Figure 24 indicate the echo envelope intensities recorded for several values of $t_1 = \tau_n$. The full sublevel spin echo decay envelope along with a fit to a single exponential and the residuals for the fit are also shown in Figure 24. These sublevel echoes and envelope decay were recorded for the $\nu_+ = 30.19$ MHz ENDOR transition. This corresponds to the proton NMR transition for the α proton of the $\cdot\text{CH}(\text{COOH})_2$ radical molecule which is shifted to the high-frequency side of the proton Larmor frequency. The sublevel T_{2n} decay time obtained from the single exponential fit shown

Figure 24 The sublevel spin echo decay recorded with $t_1 = \tau_n$ along with the fit to a single exponential and the residuals of the fit. (Reproduced by permission of the American Chemical Society from H. Thomann and M. Bernardo, in 'Advances in Chemistry Series 229: Magnetic Resonance of Carbonaceous Solids', eds. R. E. Botto and Y. Sanada, Washington, DC, 1993, Chap. 4)

in Figure 24 is 60 μ s. The proton T_{2n} values measured for $\nu_{\text{rf}} = \nu_n$ are shorter than the values measured at frequencies shifted away from the proton Larmor frequency.

Similar results have been obtained in sublevel nuclear T_{2n} studies of protons in coal samples.⁴⁶ In these coal studies, the ESR detected sublevel T_{2n} values measured at $\nu_{\text{rf}} = \nu_n$ were similar to the value measured directly by NMR.⁶⁸ The ESR detected sublevel T_{2n} values increased for NMR transitions shifted further away from the proton Larmor frequency. Apparently the time-dependent local magnetic field from the hyperfine interaction is not an effective sublevel T_{2n} relaxation mechanism. The T_{2n} value measured directly by NMR is determined by the proton homonuclear dipolar coupling. The equivalence of the value measured in the ESR detected sublevel T_{2n} experiment for $\nu_{\text{rf}} = \nu_n$ suggests that the T_{2n} value is also determined by the proton dipolar interaction with the hyperfine coupling serving only as a mechanism for detecting the sublevel coherence signal. Quite different results can be expected if the time dependence of the local field is an effective T_{2n} mechanism. In this case the T_{2n} values would be expected to decrease as the NMR transition frequency is shifted away from the proton Larmor frequency.

3.3 Coherence Transfer ENDOR

In analogy to the coherence transfer experiments known in NMR spectroscopy, it is also possible to detect the hyperfine sublevel transitions by an electron–nuclear double resonance coherence transfer experiment.^{41,43,69} Three different pulse sequences for coherence transfer ENDOR experiments are shown in Figure 25. The basic principle in all three types of experiment is similar. The rf pulses applied during the period of free precession of the electron spin coherence created by a $\pi/2$ microwave pulse interfere with the refocusing of this electron coherence following the microwave π pulse.

Figure 25 Pulse sequences for coherence transfer ENDOR

This occurs if the rf pulse is on resonance with an NMR transition that has a sublevel in common with the electron spin eigenlevel that belongs to the states from which the electron spin coherence was created. In this case, the sublevel NMR transition shifts the phase of the electron spin coherence which is detected as an attenuation of the electron spin echo. If the rf pulse is a π pulse the electron spin echo intensity is reduced to zero resulting in $\Delta\chi_e/\chi_e = 1$. If the rf pulse is a 2π pulse, the echo intensity changes sign resulting in $\Delta\chi_e/\chi_e = 2$. If a 4π pulse is applied, the electron spin echo intensity returns to its original intensity. This response of the electron spin echo intensity to the rotational symmetry of the sublevel nutation angle is called the ‘spinor property’ and is a property of wavefunctions for spin- $\frac{1}{2}$ particles.

The ENDOR spectrum recorded using the pulse sequence shown in Figure 25(a) is sufficient to observe the coherence transfer ENDOR effect. However, the application of a single rf pulse also produces a large Bloch–Siegert (BS) frequency shift $\omega_{BS} = -\gamma_e(B_2^2/B_0)$, which results in a phase shift of $\omega_{BS}t_p^{rf}$. Since the rf magnetic field strength is not constant as a function of frequency across the ENDOR spectrum, the Bloch–Siegert phase shift is observed as a broad feature, as shown in Figure 26(a), which can mask the ENDOR transitions. The Bloch–Siegert phase shift can be refocused by applying a second rf pulse, as shown in Figure 25(b), which is symmetrically displaced about the microwave refocusing pulse. This eliminates the broad feature in the ENDOR spectrum as shown in Figure 26(b). The maximum ENDOR effect of $\Delta\chi_e/\chi_e = 1$ is observed when the two rf pulses are π pulses. The efficiency of the ENDOR effect can theoretically be increased to $\Delta\chi_e/\chi_e = 2$ if the two rf pulses are 2π pulses but with a 90° shift introduced, as shown in Figure 25(c).^{41,43} The enhancement in the ENDOR signal intensity is shown in Figure 26(c). In practice, the ENDOR efficiency is improved for this phase shifted spinor ENDOR pulse sequence, but because of technical limitations (primarily pulse imperfections) the increase in efficiency is much smaller than theoretically expected. Another limitation of coherence transfer ENDOR experiments is that the ENDOR lines are usually power broadened because of the short electron phase memory time encountered for most samples. It is rare that phase memory times are longer than a few microseconds, even at liquid

Figure 26 Coherence transfer single crystal ENDOR spectra of the malonic acid radical recorded with corresponding pulse sequences shown in Figure 25. (Reproduced by permission of the American Chemical Society from C. Gemperle and A. Schweiger, *Chem. Rev.*, 1991, **91**, 1481)

helium temperatures. Nevertheless, the coherence transfer ENDOR experiment has revealed fundamentally interesting properties of the spin dynamics of the electron–nucleus spin system.

4 CONCLUDING REMARKS

ENDOR and the extension to PE NMR spectroscopy are presently tools of the specialist. They are very powerful techniques in specific cases where the spectra and/or spin dynamics for the nuclei of interest are strongly influenced by the large local magnetic fields originating from the hyperfine coupling with unpaired electron spins. In such cases the NMR transition frequencies are shifted by very large values when compared with NMR spectra of diamagnetic samples. When these circumstances do apply, ENDOR and PE NMR spectroscopy are often the only techniques which can provide the desired information. In this review we have included examples of applications in organic solids, metallobiochemistry, and organometallic chemistry. With the introduction of pulsed excitation techniques, extension to multiple irradiation frequencies, and the introduction of commercially available pulsed instrumentation, continued development of the methodology and an increasing range of applications can be expected for these techniques in the near future. Recent developments in high-frequency ESR,⁷⁰ including the extension to high-frequency ENDOR,⁷¹ will also likely expand the range of research applications. The combination of pulsed ESR and pulsed NMR should continue to be a vibrant area of research as new technology becomes available and as new methodologies and applications are developed.

1 INTRODUCTION

Magnetization transfer is a rapid reaction technique which can be used to measure enzyme-catalyzed fluxes with rate constants of the order of $1\text{--}10\text{ s}^{-1}$. These measurements can be made not only in vitro but also in some cases in an intact living system, where this might be anything from microbial cells growing in culture to specific regions of the human brain. The techniques for measuring transfer of magnetization, which were discussed in detail and applied by Forsén and Hoffman,¹ were first applied to an enzyme-catalyzed reactions in vitro by Brown and Ogawa who measured exchange in the reaction catalyzed by adenylate kinase,² and by Brown and Cheshnovsky, who measured the rate of the reversible hydration of acetaldehyde catalyzed by carbonic anhydrase.⁵⁴ The first measurements made in vivo were also made by Brown and co-workers, who measured flux between inorganic phosphate (Pi) and adenosine triphosphate (ATP) in cells of the bacterium, *Escherichia coli*.³ Since that time there have been numerous magnetization transfer studies of enzyme-catalyzed exchange both in vitro and in vivo. These have been discussed in a number of reviews.^{4–7} I will concentrate here on applications of the technique in ³¹P NMR measurements in vivo. Applications in whole body MR spectroscopy are also discussed elsewhere in the Encyclopedia.

2 THEORY AND EXPERIMENTAL METHODS

When the exchange rate constant is comparable to the spin–lattice relaxation rate and separate resonances are observed for the exchanging species then it is possible to determine the rate of exchange by measuring the transfer of nuclear polarization from one resonance to another. In ³¹P NMR measurements in vivo, the spin–lattice relaxation rates are of the order of $0.1\text{--}1\text{ s}^{-1}$.

Consider a two-site exchange system in which a nucleus exchanges between two sites, A and B.

The z magnetizations of the A (M_A) and B (M_B) spins are described by the Bloch equations, which have been modified to include this exchange:

$$dM_A/dt = -\rho_A(M_A - M_0^A) - k_{+1}M_A + k_{-1}M_B \quad (2)$$

$$dM_B/dt = -\rho_B(M_B - M_0^B) - k_{-1}M_B + k_{+1}M_A \quad (3)$$

where M_0^A and M_0^B are the equilibrium z magnetizations of the A and B spins and ρ_A and ρ_B are their spin–lattice relaxation rates. The solutions of these equations are:

$$M_{A(t)} = C_1 \exp(\lambda_+ t) + C_2 \exp(\lambda_- t) + M_0^A \quad (4)$$

$$M_{B(t)} = C_3 \exp(\lambda_+ t) + C_4 \exp(\lambda_- t) + M_0^B \quad (5)$$

where $C_3 = C_1(\lambda_+ + \rho_A + k_{+1})/k_{-1}$ and $C_4 = C_2(\lambda_- + \rho_A + k_{+1})/k_{-1}$ and the constants C_1 and C_2 are determined by the values of M_A and M_B at $t = 0$. The quantities λ_+ and λ_- are given by:

$$\begin{aligned} \lambda_{+/-} = 1/2(-(\rho_A + k_{+1} + \rho_B + k_{-1}) \\ + / - \{[(\rho_A + k_{+1}) - (\rho_B + k_{-1})]^2 + 4k_{+1}k_{-1}\}^{1/2}) \end{aligned} \quad (6)$$

Equations for exchange between three or more sites are of the same form as equations (2) and (3). Although there are no analytical solutions for systems containing more than four sites,⁷ it is straightforward to solve the equations numerically.

There are several magnetization transfer experiments which can be used to measure the exchange rates in a simple two-site exchange system.⁸

2.1 Selective Inversion

If a selective 180° pulse is applied to the B spin then in general its resonance will undergo a nonexponential recovery towards its equilibrium value while the intensity of the A resonance undergoes a transient decrease in intensity. The z magnetization of the A spin at time t is given by:

$$M_{A(t)} - M_0^A = \frac{-2M_0^B k_{-1}}{\lambda_+ - \lambda_-} [\exp(\lambda_+ t) - \exp(\lambda_- t)] \quad (7)$$

while the magnetization of the B spin is given by:

$$\begin{aligned} M_{B(t)} - M_0^B = \frac{-2M_0^B}{\lambda_+ - \lambda_-} [(\rho_A + k_{+1} + \lambda_+) \exp(\lambda_+ t) \\ - (\rho_A + k_{+1} + \lambda_-) \exp(\lambda_- t)] \end{aligned} \quad (8)$$

The exchange rate constants can be obtained either by fitting the data to these solutions or initial rates can be measured to give $(\rho_B + k_{-1})$ for B and k_{+1} for A.^{2,9} A selective inversion pulse can be obtained by using a relatively long, low power pulse. However for those spectrometers which lack the facility to produce low power pulses, selective inversion can also be obtained by using hard pulses in the DANTE sequence¹⁰ or

by using a shortened one-dimensional (1D) version of the two-dimensional (2D) exchange experiment, which is described in Section 2.3. In the latter case the pulse sequence is: $\pi/2_x - t_1 - \pi/2_x$, where $t_1 = \frac{1}{2}\Delta\nu$ and $\Delta\nu$ is the difference in resonance frequencies of the A and B spins. If the transmitter frequency is set to the resonant frequency of the A spin then at the end of this sequence the A magnetization will lie along the $-z$ axis while the B magnetization is returned to the $+z$ axis.¹¹

2.2 Selective Saturation

If the B spin is selectively irradiated (such that $M_B = 0$ at $t = 0$) for a time, t , then the observed intensity of the A resonance decays with a time constant $\rho_A + k_{+1}$ and reaches a new equilibrium value:

$$M_{(t=\infty)}^A = \frac{\rho_A M_0^A}{(\rho_A + k_{+1})} \quad (9)$$

Thus both ρ_A and k_{+1} can be calculated. The saturation pulse can be generated either by using a long, low power pulse or by using hard pulses in the DANTE sequence. Although instantaneous saturation is incompatible with the mechanism of saturation, it can be approximated by using a relatively large irradiating field strength.¹² The limit imposed on the amplitude of the saturating field is set by the requirement that the saturating pulse should be selective. Too large a saturating field will result in nonspecific saturation of the observed resonance leading to decreases in its steady-state magnetization (M_{∞}^A) and apparent spin-lattice relaxation time.¹³ Both effects will lead to an overestimation of the exchange rate. This experiment, which is sometimes referred to as the time-dependent saturation transfer experiment, has two variants which have also been used to measure enzyme-catalyzed exchange. In these experiments the steady state and equilibrium magnetizations of the nonirradiated spin ($M_{(t=\infty)}^A$ and M_0^A , respectively) are measured in order to obtain the ratio $\rho_A/(\rho_A + k_{+1})$ [see equation (9)]. The sum, $(\rho_A + k_{+1})$ is then determined in separate experiments by measuring the z magnetization of the A spin following either its inversion or saturation in the presence of saturation of the B spin. The A magnetization relaxes exponentially toward its steady-state value ($M_{(t=\infty)}^A$) with a time constant $(\rho_A + k_{+1})$. The relative accuracy of the kinetic parameters derived from these experiments in a given amount of time have been compared using simulated data.¹⁴ The choice of which particular saturation transfer experiment to use depends on the rate constant to be measured and the T_1 of the observed resonance.

2.3 Two-Dimensional Exchange Experiments

The two-dimensional exchange experiment introduced by Jeener et al.¹⁵ uses the following pulse sequence: $\pi/2 - t_1 - \pi/2 - t_m - \pi/2 - t_2$. The first two pulses frequency label the z magnetization. Transfer of this magnetization between the A and B spins due to cross relaxation or chemical exchange during the t_m period is then detected during the t_2 period following the third 90° pulse. These signals are recorded for regular increments of t_1 and the resulting matrix of free

induction decays is then double Fourier transformed to produce a 2D spectrum. Magnetization that has exchanged between the A and B sites will appear as cross peaks while the diagonal peaks represent magnetization which has failed to migrate. Cross peaks arising from coherent magnetization transfer due to scalar coupling are eliminated by phase cycling the pulses.¹⁶ The amplitudes of the peaks in the 2D spectrum are described by equations similar to those that describe signal intensities in the selective inversion experiment.⁷ In early applications of the technique the exchange rate constants were estimated by recording 2D spectra at a series of t_m values and fitting the observed cross-peak intensities versus t_m to the appropriate exchange equation. Alternatively the rate constants can be estimated from the initial rate of cross-peak buildup, which is equal to k_{+1} (or k_{-1}). Recording a series of 2D spectra is extremely time consuming and therefore a method of analysis was developed to determine the rate constants from a single 2D exchange spectrum.

The 2D spectrum can be described by the following equation:

$$\mathbf{M} = \exp(\mathbf{R}t_m)\mathbf{M}_0 \quad (10)$$

where $\mathbf{M}$ is a matrix comprising the peak volumes in the spectrum and $\mathbf{R}$ is the matrix of exchange and relaxation rate constants. For the simple two-site exchange system described above, $\mathbf{R}$ has the form:

$$\mathbf{R} = - \begin{bmatrix} \rho_A + k_{+1} & -k_{-1} \\ -k_{+1} & \rho_B + k_{-1} \end{bmatrix} \quad (11)$$

$\mathbf{M}_0$ is a diagonal matrix representing the 2D spectrum obtained with $t_m = 0$. This is usually replaced with $\alpha\mathbf{S}_0$, where $\mathbf{S}_0$ is the diagonal matrix of mole fractions obtained from a fully relaxed 1D experiment and α is an unknown scaling factor. Replacing $\mathbf{M}_0$ with $\alpha\mathbf{S}_0$, which avoids collecting another 2D spectrum, gives rise to false values for the diagonal elements in the $\mathbf{R}$ matrix but leaves the off-diagonal elements, which specify the exchange rate constants, unaffected. This method, which has been termed 'back transformation'^{17,18} and a 1D counterpart derived from it,¹⁹ essentially involve fitting an exponential function to a data set consisting of only two time points. These are the magnetizations (signal intensities) of the exchanging species when $t_m = 0$ and when t_m is set at some other value. The value of t_m which will give the most precise estimate of the exchange rate constants, has been estimated to be equal to $1/(R + k)$, where R and k are the mean values of the relaxation and exchange rate constants, respectively.²⁰ The back transformation method has been used to estimate the exchange rate constants in the reactions catalyzed by adenylate kinase and phosphoglycerate mutase in vitro.²¹

Exchange rate constants can also be obtained from a single 2D exchange spectrum by using the 'accordion' experiment described by Bodenhausen and Ernst.²² This is a modification of the 2D experiment in which the t_m period is incremented in steps of t_1 and the rate constants are obtained by analysis of the lineshapes in the resulting 2D spectrum. If, in the two-site exchange system discussed above, ρ_A and ρ_B and the concentrations of the A and B spins are equal then the diagonal peaks in the accordion spectrum will have a lineshape which is given by the sum of two Lorentzian lines with linewidths ρ and $(k_{+1} + k_{-1} + \rho)$ while the cross-peak lineshapes are given

by the difference between these two Lorentzian lines. This analysis of the accordion experiment was used to estimate the exchange rate constants in the reaction catalyzed by creatine kinase *in vitro*.²³ Analysis of the accordion experiment in a more typical case, where the populations of the exchanging spins are unequal and the relaxation rate constants are different has been considered by Kuchel.⁷

2.4 Comparison of 1D and 2D Methods

Two-dimensional methods have the advantage that in multisite exchange systems they can, in principle, detect all the exchanges in a single experiment. The 2D exchange experiment and its 1D counterpart also have the advantage that they use nonselective pulses and therefore avoid the problems associated with the limited selectivity of the irradiating field in the 1D experiments. All the methods described require some preliminary estimate of the exchange rate constant in order to optimize the experimental protocol, for example to choose the optimal t_m in the 2D experiments or the optimal saturation transfer protocol in the 1D experiments. For experiments *in vivo*, where limited sample viability precludes long data acquisition times, the 1D methods are preferred over the more time consuming 2D methods. This is reflected in the fact that although 2D exchange experiments have been performed,²⁴ the overwhelming majority of magnetization transfer measurements *in vivo* have employed 1D methods.

2.5 Effect of the Equilibrium Constant on Exchange Measurements

In the selective inversion and 2D experiments, which follow the z magnetization of the exchanging species after a transient perturbation, the amplitude of these changes depends on the mole fractions of both species. This is illustrated by equation (7) for the inversion transfer experiment. This is not the case in a saturation transfer experiment in which changes in the z magnetization of the A spin are independent of the concentration of the B spin [see equation (9)]. Thus a saturation transfer experiment may detect exchange between a metabolite present in high concentration and one present in low concentration, even if the latter is so low in concentration as to be undetectable in the NMR spectrum. This is illustrated by the saturation transfer spectra, obtained from the dog heart *in vivo*, shown in Figure 1. Saturation of the γ -phosphate resonance of ATP also results in saturation of the β -phosphate resonance of adenosine diphosphate (ADP), which is less than 1 ppm upfield and which is too low in concentration to be observable in these spectra. Exchange between the β -phosphate of ADP and the β -phosphate of ATP results in a decrease in the resonance intensity of the latter. The lower limit on the concentration of the metabolite to which flux can be measured is imposed by the amount of power required to achieve saturation of the nucleus in this site. For any given flux, as the concentration of the metabolite is decreased the residence time of the nucleus in this site will also decrease and the irradiating field required to achieve its saturation will increase. This was demonstrated experimentally with a study of ATP–ADP exchange catalyzed by creatine kinase *in vitro*.²⁵

Figure 1 ^{31}P NMR saturation transfer spectra of the dog heart *in vivo*. The spectra were acquired using a surface coil placed over the heart. Saturation of the γ -phosphate resonance of ATP results in transfer of magnetization to the phosphocreatine and P_i resonances. This is manifest as a decrease in their resonance intensities [compare spectra (a) and (b)], which is clearly seen in the difference spectrum (c). The decrease in the β -phosphate resonance of ATP is due to exchange between ADP and ATP (see text). The decrease in the α -phosphate resonance, which has also been observed in a number of other studies and which cannot be explained by the lack of selectivity of the saturating field, is unexplained. Abbreviations: PDE, phosphodiester; PCr, phosphocreatine; γ -ATP, γ -phosphate resonance of ATP; α -ATP, α -phosphate resonance of ATP; β -ATP, β -phosphate resonance of ATP. 2.6 Assumptions Made in Analyzing Magnetization Transfer Data

2.6.1 Two-Site Exchange

Magnetization transfer measurements of exchange between two substrates in an enzyme-catalyzed reaction are frequently

analyzed using the two-site exchange model described above. Enzyme-bound intermediates in the exchange reaction, which in general will be very low in concentration compared with the free substrates and therefore turning over very rapidly, can usually be ignored. However an intermediate could affect the measured exchange velocity if there was rapid loss of the magnetic label at this site, i.e. if the T_1 of the exchanging nucleus in this site were very short. Although modeling studies have shown that the T_1 would have to be very short,²⁵ and there appears to be no evidence for this from ^{31}P NMR studies of enzyme-bound substrates, there are now two independent reports that indicate that this may occur in the exchange between ATP and ADP catalyzed by creatine kinase in vitro.^{25,26} These compared isotope exchange measurements with magnetization transfer measurements and showed that under some conditions the latter underestimated the exchange rate. However it should be emphasized that for the exchange most often measured in vivo, i.e. that between phosphocreatine and ATP, there was good agreement between the isotope exchange and magnetization transfer data.

2.6.2 Relationship Between Measured Exchange and Net Flux

Since the magnetization transfer experiment, like an isotope exchange experiment, only measures exchange between a pair of substrates there need be no direct relationship between this exchange flux and the metabolically relevant net flux catalyzed by the enzyme. Consider, for example, the reaction mechanism of creatine kinase, which is illustrated in Figure 2. Magnetization transfer measurements of exchange between ATP and ADP and between phosphocreatine and ATP and isotopic measurements of exchange between ATP and ADP, between PCr and ATP and between PCr and Cr have been shown to be similar under most conditions, consistent with rate-limiting interconversion of the two ternary complexes (E.MgADP.PCr and E.MgATP.Cr).^{25,26} Therefore under these conditions it is valid to equate magnetization transfer measurements of PCr $\leftrightarrow$ ATP exchange with net flux in the reaction since the same step, the interconversion of the ternary complexes, is rate-limiting for all the exchanges and for the net flux catalyzed by the enzyme. However at high [PCr]/[Cr] ratios (above 2) the ATP $\leftrightarrow$ PCr exchange flux exceeds the ADP $\leftrightarrow$ ATP exchange flux, indicating that control has shifted from the interconversion of the ternary complexes to the steps of substrate–enzyme complex formation and breakdown.

Magnetization transfer measurements of steady-state ATP turnover appear to be measuring net flux. The evidence for this has come from the correspondence between P:O ratios

(moles of ATP synthesized: atoms of oxygen consumed) measured in the cell with those measured in suspensions of isolated mitochondria catalyzing net ATP synthesis (discussed in Section 3.2). However, evidence has been obtained recently that mitochondria in vivo can catalyze an ATP $\leftrightarrow$ Pi exchange reaction under some conditions.

3 FLUXES MEASURED IN VIVO

3.1 Creatine Kinase

Creatine kinase catalyses the reaction:

The enzyme is abundant in muscle and neural tissue, where the reaction is normally near-to-equilibrium.²⁷ When an energy demand is placed on the tissue, the ATP concentration is maintained at the expense of phosphocreatine. Phosphocreatine thus acts as an energy store, buffering temporal changes in the ATP and ADP concentrations.

3.1.1 The Shuttle Hypothesis

A second role for the enzyme has been proposed based on the observation that the enzyme is spatially localized (reviewed by Wallimann et al.²⁷). For example in muscle, concentrations of the enzyme are found at the myofibrils and at the mitochondria. In the latter case there is a distinct mitochondrial isoform which is located in the intermembrane space. According to the ‘shuttle hypothesis’ phosphocreatine also acts as a spatial energy buffer, shuttling energy between the sites of production, the mitochondria, to the sites of utilization, in muscle the myofibrillar Mg^{2+} -ATPase. In its simplest form phosphocreatine and creatine are thought to act as parallel diffusion pathways for the diffusion of ATP and ADP, respectively, between the mitochondria and myofibrils.²⁸ More elaborate models take into account the apparent functional interactions between the enzyme and other proteins in the muscle. For example there is good evidence that the mitochondrial isoform interacts directly with the adenine nucleotide translocase in the inner mitochondrial membrane, resulting in channeling of mitochondrially-generated ATP between the two proteins.²⁷ Inevitably ^{31}P NMR magnetization transfer measurements of creatine kinase kinetics in vivo have been used to look for evidence of the shuttle.

Studies in the perfused heart, which showed an increase in the reaction velocity with increased ATP turnover despite only small changes in the enzyme’s steady state substrate concentrations, indicated a discrepancy with the solution properties of the enzyme.^{29,30} A similar increase in creatine kinase flux with increased ATP turnover has also been observed in brain.³¹ Measurements in neonatal rabbit hearts, at different stages of development, showed that the reaction velocity increased as the concentration of the mitochondrial isoform increased,³² a result which is consistent with the shuttle hypothesis and with functional coupling between the mitochondrial isoform and the adenine nucleotide translocase. This study also showed, as expected from the solution properties of the enzyme, that flux increased with the increase

Figure 2 Reaction mechanism of creatine kinase. E represents free enzyme; PCr represents phosphocreatine and Cr represents creatine; MgADP and MgATP represent the Mg^{2+} -bound forms of ADP and ATP respectively

in creatine and phosphocreatine contents that occurred during development. These data may explain why in skeletal muscle, which contains only 2% mitochondrial creatine kinase activity, there is no increase in creatine kinase reaction velocity with increased work.^{33,34} Further evidence for compartmentation of creatine kinase came from the observation that in a time-dependent saturation transfer experiment the decay of the phosphocreatine resonance was not always a single exponential. A kinetic model developed to explain these data attributed this to a nonsaturable mitochondrial pool of ATP in exchange with phosphocreatine in the reaction catalyzed by the mitochondrial isoform.³⁵ More recent work in the heart has shown that the presence of the mitochondrial isoform is not a prerequisite for the increase in creatine kinase flux with work. Increased flux was shown to result from changes in the enzyme's substrate concentrations. However there was, in addition, an unexplained change in the kinetic properties of the enzyme between rest and work.³⁶

The role of creatine kinase in the shuttle has also been investigated by feeding animals creatine analogs which accumulate in cardiac and skeletal muscle and which inhibit the enzyme.^{37,38} Magnetization transfer measurements of creatine kinase fluxes in these muscles, which were less than or comparable to the ATP turnover rates, showed that phosphocreatine could not be an obligatory intermediate in energy transduction. However it is now clear that during the long feeding periods required, skeletal muscle undergoes compensatory metabolic adaptations.³⁹ Furthermore in heart, it was subsequently shown that the presence of a creatine analog does in fact impair muscle function.⁴⁰

Further information about the role of creatine kinase in muscle function will undoubtedly come from using NMR magnetization transfer techniques in conjunction with molecular genetic methods for manipulating the tissue concentrations of the enzyme. For example the role of the different isoforms in muscle function is being investigated by changing their expression in the skeletal muscle of transgenic mice.⁴¹ Elimination of the M isozyme, using gene targeting techniques, was shown totally to eliminate magnetization transfer between phosphocreatine and ATP.⁴² Remarkably the phosphocreatine levels declined normally during exercise. Presumably this was due to the residual mitochondrial creatine kinase activity present. Interestingly the muscle adapted to the absence of the M isoform and these adaptations show some similarities to those observed in muscle of analog-fed animals.

3.1.2 Differences in the Forward and Reverse Fluxes

Despite the fact that the reaction catalyzed by creatine kinase is normally near-to-equilibrium there have been numerous magnetization transfer studies which have shown that the forward and reverse fluxes are unequal. Two models have been proposed to explain this difference. One proposes that there are two pools of ATP, a large pool and a small pool which are both in exchange with phosphocreatine. Saturation of the observed γ -phosphate resonance of ATP allows measurement of flux from phosphocreatine to both pools of ATP. However the converse is not true since saturation of the phosphocreatine resonance will result in flux being measured predominantly between the large ATP pool and phosphocreatine. This model was elaborated in terms of the shuttle hypothesis, where the cytosolic ATP pool constitutes the large pool and the small

pool is represented by ATP in the mitochondria and at the myofibrils.⁴³ In support of this proposal it was shown that the discrepancies in the forward and reverse fluxes reported in the literature increased as the rate of ATP synthesis increased. It was also pointed out that the forward and reverse fluxes measured in rat brain were equal if measured using a 2D exchange experiment but were unequal if measured using a saturation transfer experiment. As pointed out above, the saturation transfer experiment is capable of measuring exchange between metabolites present in very unequal concentrations whereas in a 2D exchange experiment, both exchanging pools need to be present at a significant concentration for the exchange to be observed. The second model considers the difference in the fluxes to be due to the fact that the γ -phosphate of ATP is in exchange with Pi as well as with phosphocreatine. Thus while exchange measurements of the flux from phosphocreatine to ATP can be analyzed using a two-site exchange model the reverse flux may be underestimated if not treated as a three-site exchange system, i.e. $\text{PCr} \leftrightarrow \text{ATP} \leftrightarrow \text{Pi}$. Much of the evidence which supports a compartmentation model is also compatible with this model (discussed by Brindle⁶). For example the difference in creatine kinase fluxes in this model would be expected to increase as the rate of $\text{ATP} \leftrightarrow \text{Pi}$ exchange increases. The elegant study of Ugurbil et al.⁴⁴ on the perfused working rat heart appeared to provide an answer as to which model was correct when it was shown that the forward and reverse fluxes were equal if the reverse flux was measured by saturating both the phosphocreatine and Pi resonances and employing a three-site exchange model for data analysis. However there are two problems with this experiment. As Ugurbil et al.⁴⁴ point out, the fractional reduction in the γ -phosphate resonance of ATP, when both the phosphocreatine and Pi resonances are saturated, should be equal to or less than the value observed when only the phosphocreatine resonance is saturated. This was not the case under one set of perfusion conditions. Another problem is that the measured $\text{ATP} \leftrightarrow \text{Pi}$ exchange is simply not fast enough to give the observed discrepancy.⁴⁵ An early study, which showed a difference in the forward and reverse fluxes despite the application of a correction factor which allowed for the observed exchange between ATP and Pi, concluded that the γ -phosphate of ATP must be in rapid exchange with other sites.⁴⁶

There appears at present to be no completely satisfactory explanation for the discrepancy in the forward and reverse fluxes. However, in the context of compartmentation, perhaps tissue heterogeneity should also be considered. For example, in skeletal muscle measurements of enzyme levels in individual fibers have shown extreme heterogeneity, even between adjacent fibers.⁴⁷

3.2 ATP Turnover

A significant limitation of magnetization transfer measurements *in vivo* is that very few enzyme-catalyzed fluxes are measurable. For example the spectra shown in Figure 1 illustrate almost all the exchanges that can be measured using ^{31}P NMR magnetization transfer measurements *in vivo*. However, in measuring the fluxes between Pi and ATP the technique can be used to determine arguably the most important fluxes in a living cell, ATP synthesis and hydrolysis. In early measurements of the flux between Pi and ATP it

was assumed that the flux was catalyzed solely by the mitochondrial F_1F_0 ATP synthase. However subsequent studies, in a number of systems including *E. coli*, yeast and the perfused heart, demonstrated that the coupled reaction catalyzed by the glycolytic enzymes, glyceraldehyde 3-phosphate dehydrogenase (GAPDH) and phosphoglycerate kinase (PGK) could also participate in this exchange reaction (reviewed by Brindle⁶). Elimination of this glycolytic exchange allows the $P_i \leftrightarrow$ ATP exchange catalyzed by the mitochondria to be determined. For example, a detailed study of $P_i \rightarrow$ ATP and $ATP \rightarrow P_i$ fluxes in the perfused rat heart, in which the glycolytic exchange was inhibited, either by iodoacetate treatment or by depletion of glycolytic intermediates, showed that the P:O ratio was approximately 2.4.⁴⁸ The similarity of this value to that displayed by isolated mitochondria in vitro catalyzing net ATP synthesis suggests that the mitochondrial ATP synthase is operating unidirectionally in vivo and that the technique measures net ATP turnover. The technique can thus be used to assess the degree of mitochondrial coupling in vivo. For example measurements of P:O ratios in the postischemic perfused rat heart showed that mitochondrial uncoupling, which would lead to a decrease in the measured P:O ratio, could not be the cause of the observed postischemic depression in mechanical function.⁴⁹

The measurements of $P_i \rightarrow$ ATP flux have also been used to examine the properties of the glycolytic enzymes. Studies of the perfused rat heart⁴⁹ and the dog heart in vivo⁵⁰ have shown that the activities of GAPDH and PGK are altered in the postischemic myocardium. Measurements of $P_i \rightarrow$ ATP flux in yeast cells, in which the concentration of PGK had been increased using molecular genetic techniques, allowed a detailed study of the kinetic properties of this enzyme in the intact cell. This showed that there were no unusual kinetic properties conferred on the enzyme by its cellular environment.⁵¹

Although the glycolytic exchange reaction can compromise magnetization transfer measurements of ATP turnover, particularly in the presence of glucose, this may be less of a problem in vivo. For example the glycolytic contribution to the measured $P_i \rightarrow$ ATP flux in the postischemic dog heart in vivo appeared to be much lower than that observed in postischemic glucose-perfused rat hearts.^{49,50} In rat skeletal muscle in vivo, the measured $P_i \rightarrow$ ATP flux correlated well with the work performed. Although a glycolytic contribution could not be rigorously excluded the measured flux showed good agreement with ATP turnover rates estimated from oxygen consumption measurements in the perfused hind limb and the rates of phosphocreatine breakdown during a tetanus.³⁴

Recent studies on yeast have shown that the measured $P_i \rightarrow$ ATP flux is increased in cells which have been genetically modified to overexpress an isoform of the mitochondrial adenine nucleotide translocase.⁵⁵ This increase in flux, which occurred in the absence of an increase in oxygen consumption, suggested that the mitochondria were catalysing predominantly an $ATP \leftrightarrow P_i$ exchange reaction under these conditions rather than net ATP synthesis. This interpretation of the data is in accord with an earlier radioisotope study of $ATP \leftrightarrow P_i$ exchange in isolated mammalian mitochondria which showed that, at low rates of respiration, mitochondria can catalyze an $ATP \leftrightarrow P_i$ exchange, but that at higher rates of respiration the $P_i \rightarrow$ ATP flux becomes unidirectional. Thus it is possible that in mammalian systems at low rates of respiration, even when

the glycolytic contribution has been removed, the $P_i \rightarrow$ ATP flux measured in a magnetization transfer experiment might include some contribution from a mitochondrially catalyzed $ATP \leftrightarrow P_i$ exchange.

4 CONCLUDING REMARKS

An interesting area, which I have not covered, is measurements of membrane transport (reviewed by Kuchel⁷). Of particular interest is a ^{19}F NMR study of 3-fluoro-3-deoxy-D-glucose transport across the red cell membrane.⁵² However it is not yet clear whether this technique can be applied in other systems. Another interesting study employed the ^{31}P NMR saturation transfer experiment to measure $ATP \leftrightarrow$ ADP exchange across the membrane of isolated mitochondria.⁵³ This showed that the exchange rates were more than 10 times faster than the rates previously determined using isotopic techniques and that they were almost 10 times faster than the ATP synthase ($ATP \leftrightarrow P_i$) exchange rates.

I have concentrated on ^{31}P NMR magnetization transfer measurements in vivo as this reflects my own interest, an interest which was initially stimulated by the potential of the technique to provide unique information on the kinetic properties of enzymes in vivo.

1 INTRODUCTION

The manipulation of nuclear spin systems by rf fields and/or the observation of the signal they induce in a pick-up coil nearly always starts from an initial state characterized by one or several temperatures for the nuclear spins. The simplest example, that of a spin system of Hamiltonian $\mathcal{H}$ and single spin temperature T , corresponds to a density matrix for the spins of the form

$$\sigma = \exp(-\mathcal{H}/kT)/\text{Tr}[\exp(-\mathcal{H}/kT)] \quad (1)$$

The description of more complex cases can be found in textbooks.¹⁻³

In the vast majority of the uses of NMR, the characteristic frequencies ω associated with the Hamiltonian (for instance, in the Zeeman case, the Larmor frequency) are such that we have

$$\hbar\omega \ll kT \quad (2)$$

In such a case it is permissible, for most practical purposes, to replace the exact density matrix [equation (1)] by the expansion

$$\sigma \simeq (1 - \beta\mathcal{H})/\text{Tr}(1) \quad (3)$$

where $\beta = 1/kT$ is called the ‘inverse temperature’. This is known as the ‘high-temperature approximation’, and it brings about an enormous simplification in the theoretical handling of NMR—most quantities of interest are linear in the inverse temperature β (with the exception of entropy, which is quadratic in β), so that their relative values are independent of spin temperature.

Low spin temperature NMR deals with the case when equation (2) is not valid and one has to use the full expression [equation (1)] for the density matrix. This leads to so-called ‘nonlinear effects’ in spin temperature, and eventually to nuclear magnetic ordering. There is an exception to the above statement; this is the case when equation (2) is valid as regards the nuclear frequencies, but when the nuclear spins are used

to probe the properties of systems at low temperature, which depend strongly on temperature. Examples are electronic ferro-, antiferro-, or ferri-magnets, or superfluid helium-3. These cases are explicitly omitted from the present article.

Low nuclear spin temperatures do not occur spontaneously in nature. Indeed, their production turns out to be extremely laborious, and it can only be justified by the pursuit of a valuable end. This means that, by contrast with the quasigeneral usage in the high-temperature domain, in low spin temperature NMR the nuclear spins are not used as probes of other systems [e.g. proteins or high T_c superconductors (see *High Temperature Superconductors*)], but they are the system whose properties are studied for their own sake: actors rather than spectators. The ‘valuable’ aim is essentially nuclear magnetic ordering.

After a brief description of the methods of production of low nuclear spin temperatures, we analyze some of the properties of such systems. In general, the discussion is limited to the domain of paramagnetism. Nuclear ordering, which is described elsewhere in this Encyclopedia (see *Nuclear Ferromagnetism and Antiferromagnetism* and *Thermodynamics of Nuclear Magnetic Ordering*), will only occasionally be touched upon.

This article is to a large extent inspired by Chapter 5 in the book by Abragam and Goldman,⁴ although here greater emphasis is put on the ideas behind and the principles of the formal calculations rather than on their detailed description.

2 METHODS OF PRODUCTION OF LOW NUCLEAR TEMPERATURES

The most obvious method is known under the delicate name of the ‘brute force’ method. It consists of waiting for thermal equilibrium with the lattice at a very low temperature of nuclear spins in a very high magnetic field. Let us give figures. Since both $\hbar\omega = h\nu$ and kT are energies, it is possible to express temperature in terms of frequency, and vice versa. It is useful to remember that 1 K $\simeq$ 20.8 GHz, or

$$1 \text{ mK} \simeq 20.8 \text{ MHz} \quad (4)$$

so that a ‘low’ Zeeman temperature would correspond to several millikelvin in a field of several tesla. The only problem involves the time required for the nuclear Zeeman interaction to reach equilibrium with the lattice, i.e. the length of the longitudinal relaxation time T_1 . In insulators, where nuclear relaxation is due to paramagnetic centers, T_1 becomes extremely long at low lattice temperature and in high field may reach a few hundred hours. Even though much shorter than predicted theoretically, for reasons not yet understood, such values of T_1 deprive the ‘brute force’ method of its attraction. The situation is different with metals, because their relaxation by the Korringa mechanism is much faster, and the ‘brute force’ method has been used with success for various metals. It should be noted that at high field, when the Zeeman interaction dominates all other interactions, a low spin temperature corresponds to a high nuclear polarization, through the relationship

$$P = B_I(\hbar\omega/kT) \quad (5)$$

where B_I is the Brillouin function for a nucleus of spin I . For the simplest case, i.e. spin $\frac{1}{2}$, this function is

$$B_I(x) = \tanh(x/2) \quad (6)$$

It is apparent from equation (5) that the polarization depends only on the ratio ω/T , i.e. the same physical state would be obtained with a different temperature, by varying the Larmor frequency in proportion. Therefore, the concept of temperature itself is of limited interest and for NMR in high field, ‘high-polarization NMR’ would be a more appropriate description than ‘low spin temperature NMR’. The necessity for a low lattice temperature is a mere consequence of the practical limitations on the value of the external field.

For insulators, a successful alternative to the inefficient ‘brute force’ method is dynamic nuclear polarization (DNP) which results from the EPR off-resonance irradiation of paramagnetic centers introduced purposely at low concentration in the solid. The basic phenomenon is the following: if electronic spins of Larmor frequency ω_e are irradiated at a frequency $\omega \neq \omega_e$, each time a photon is absorbed the energy of the system increases by $\hbar\omega$, and an upwards electronic spin-flip is produced, resulting in an increase in the electronic Zeeman energy of $\hbar\omega_e$. The energy imbalance $\hbar(\omega_e - \omega)$ serves eventually to modify the Zeeman energy of the nuclear spins.

In its first version, corresponding to the so-called ‘solid effect’,⁵ the irradiation frequency is the difference between or the sum of the electronic and nuclear Larmor frequencies $\omega_e \pm \omega_n$. The transitions are ‘forbidden’ flip-flop transitions or flip-flip transitions of an electron and a nuclear spin, which can only take place due to the dipolar interaction between these spins. Flip-flop transitions at $\omega_e - \omega_n$ yield a nuclear polarization parallel to the equilibrium value, and flip-flip transitions at $\omega_e + \omega_n$ yield a nuclear polarization of opposite sign. Under strong irradiation and in the absence of parasitic nuclear relaxation, the nuclear polarization modulus eventually becomes equal to that of the thermal equilibrium electronic polarization.

In many cases, when the EPR linewidth exceeds the nuclear Larmor frequency ω_n , the mechanism of DNP is different: off-resonance microwave irradiation produces allowed electronic transitions which lead to a cooling of the electron spin–spin reservoir. As this reservoir is in thermal contact with the nuclear Zeeman reservoir, the latter also becomes cooled, resulting in an increase in its polarization modulus. The sign is the same as for the solid effect: for $\omega < \omega_e$ it corresponds to a positive spin temperature and for $\omega > \omega_e$ to a negative spin temperature. Detailed descriptions of DNP are given by Abragam and Goldman.^{4,6}

Physicists are interested not only in nuclear spins with low Zeeman temperatures, but also in spins whose low temperature affects their spin–spin interactions: dipolar, indirect (in heavy nuclei), or RKKY^{1,3} (in metals). One can start from nuclei with large polarizations (low Zeeman temperatures) and perform an adiabatic demagnetization. This has been done for ‘brute force’ polarized nuclei^{7,8} and DNP-polarized nuclei in insulators (see e.g. Abragam and Goldman,⁴ Chapters 5 and 8). The adiabatic demagnetization can be done by actually reducing the field to zero, in which case the final interactions are the full spin–spin interactions. It can also be done at high field, by slowly sweeping an rf field from a frequency far off-resonance down to on-resonance. As a result of this

adiabatic demagnetization in the rotating frame (ADRF),⁹ it is the effective field in the rotating frame that is reduced to zero, and the remaining interactions are the so-called ‘secular spin–spin interactions’, consisting of that part of the spin–spin interactions which commutes with the Zeeman coupling.^{1,2}

In zero field, either actual or effective, the nuclear polarization vanishes, and ‘high-polarization NMR’ is no longer an adequate description. One quantity that is conserved in adiabatic demagnetization is the entropy of the system. The large initial nuclear polarization corresponds to a low entropy, and the only adequate title for this article should therefore be ‘low-entropy NMR’.

3 THE RESONANCE SIGNAL

It is well known from general principles (i.e. linear response theory¹⁰) that the CW nuclear absorption signal is the Fourier transform of the FID signal observed after an infinitely small pulse θ (see e.g. Goldman,¹¹ Chapter 1). It is then sufficient to analyze the signal observed after such a pulse.

We consider, for simplicity, a system with Zeeman and dipolar interactions having a density matrix of the form

$$\sigma_0 = \exp\left(-\sum_{\mu} \beta_{\mu} Z_{\mu} - \beta_D \mathcal{H}'_D\right) / \text{Tr}\{\exp(\dots)\} \quad (7)$$

where Z_{μ} is the Zeeman interaction $\omega_{\mu} I_z^{\mu}$ of the nuclear species μ , β_{μ} is the corresponding inverse spin temperature, $\mathcal{H}'_D$ is the secular dipolar interaction, and β_D its inverse temperature. This is transformed by a pulse θ at the Larmor frequency of species 0 into

$$\sigma(0) = \exp(-i\theta I_x^0) \sigma_0 \exp(i\theta I_x^0) \quad (8)$$

Its subsequent evolution is

$$\sigma(t) = \exp(-i\mathcal{H}t) \sigma(0) \exp(i\mathcal{H}t) \quad (9)$$

where $\mathcal{H}$ is the (supposedly static) Hamiltonian. In an appropriate rotating frame, $\mathcal{H}$ reduces to $\mathcal{H}'_D$. The expectation value of a quantity Q is

$$\langle Q \rangle(t) = \text{Tr}\{Q\sigma(t)\} \quad (10)$$

When the angle θ is infinitely small, equation (8) yields, to first order (linear response)

$$\sigma(0) \simeq \sigma_0 - i\theta [I_x, \sigma_0] \quad (11)$$

and the FID signal $\langle I_+ \rangle(t)$ (a transverse vector expressed in the form of a complex number) becomes

$$\langle I_+ \rangle(t) = -i\theta \text{Tr}\{I_+ \exp(-i\mathcal{H}'_D t) [I_x, \sigma_0] \exp(i\mathcal{H}'_D t)\} \quad (12)$$

or, after a few manipulations,

$$\langle I_+ \rangle(t) = -i\theta \langle [I_+(t), I_x] \rangle_0 \quad (13)$$

with the notation

$$Q(t) = \exp(+i\mathcal{H}'_D t) Q \exp(-i\mathcal{H}'_D t) \quad (14)$$

$$\langle Q \rangle_0 = \text{Tr}\{Q\sigma_0\} \quad (15)$$

3.1 Difference of the High-Temperature Case

We consider, for simplicity, a density matrix corresponding to pure Zeeman order for a system of identical spins $\frac{1}{2}$, I_i :

$$\begin{aligned}\sigma_0 &= \exp\left(-\beta \sum I_z^i\right) / \text{Tr}\left\{\exp\left(-\beta \sum I_z^i\right)\right\} \\ &= \prod_i (1 - t_\beta I_z^i)\end{aligned}\quad (16)$$

where

$$t_\beta = \tanh\left(\frac{1}{2}\beta\omega_0\right) \quad (17)$$

This is transformed by the θ pulse [equation (8)] into

$$\sigma(0) = \prod_i [1 - t_\beta (\cos\theta I_z^i + \sin\theta I_y^i)] \quad (18)$$

The FID of spin I_i , which is representative of the total FID, is then

$$\langle I_+^i \rangle = -t_\beta \sin\theta \text{Tr} \left\{ I_+^i(t) I_y^i \prod_{j \neq i} [1 - t_\beta (\cos\theta I_z^j + \sin\theta I_y^j)] \right\} \quad (19)$$

In the low θ limit, pertaining to the analysis of the absorption signal, this yields

$$\langle I_+^i \rangle = -t_\beta \theta \text{Tr} \left\{ I_+^i(t) I_y^i \prod_{j \neq i} (1 - t_\beta I_z^j) \right\} \quad (20)$$

It is easily shown that this is identical to equation (13). At high temperature, $t_\beta \simeq \frac{1}{2}\beta\omega_0 \ll 1$, so that $\prod_j (\dots) \simeq 1$, and one obtains

$$\langle I_+^i \rangle = -\frac{1}{2}\beta\omega_0\theta \text{Tr}\{I_+^i(t) I_y^i\} \quad (21)$$

It is the fact that t is no longer negligible at low temperature which distinguishes the low-temperature case from the high-temperature one. We end this subsection by emphasizing two of the conspicuous consequences of this difference:

1. It is apparent from equation (19) that, even with one nuclear species and purely Zeeman initial order, the FID shape does depend on the pulse angle θ . This observation has had two main consequences.
 - (i) A great surprise, after its experimental discovery, for a Ph.D. student of J. S. Waugh (private communication).
 - (ii) A disproof, or rather a correction, of the so-called ‘Lowe–Norberg theorem’¹² that the CW signal is the Fourier transform of the FID signal. This theorem stems from the fact that under the two conditions of high temperature and purely Zeeman order the FID signal following a rf pulse is proportional to $\sin\theta$, but its shape is independent of θ , as can be seen from equation (21). This fact, which was known earlier [E. M. Purcell, NMR Lectures Notes, Harvard (1953); A. Abragam, NMR Lectures Notes, Saclay (1955)], is really an extension of the validity of a general theorem that the CW signal is the

Fourier transform of the FID signal following a pulse of infinitely small angle θ , a consequence of linear response theory¹⁰ (see also Abragam and Goldman,⁶ Chapter 1, and Goldman,¹¹ Chapter 1).

2. In the case when there are several different polarized nuclear species, and/or secular dipolar order (nonnegligible β_D) in addition to Zeeman order, the FID signal shape of *one* nuclear species depends on *all* spin temperatures. It should be noted that, in the case of Zeeman plus dipolar order, the FID signal of spins I_μ depends on both β_μ and β_D , and on the angle θ , even at high temperature.²

3.2 Qualitative Features of the Zeeman Signal

We refer again to the FID signal following a pulse of infinitely small angle θ , but starting from a state of pure Zeeman order [$\beta_D = 0$ in equation (7)]. By contrast with the high-temperature case, the absorption signal shape is, in general, not symmetrical, and not centered on the Larmor frequency. This manifests itself by the fact that this CW signal has no vanishing odd moments. This can be shown by simple qualitative arguments that are not given here. Furthermore, all moments, whether odd or even, depend on the polarization, i.e. the shapes of the FID signal or absorption signal depend on the polarization. There is, however, a property of the high-temperature case that remains true for low temperature: the area of the absorption signal of a given nuclear species is proportional to its polarization. (This is also the initial FID signal following a small θ pulse). This property, which is associated with the polarization dependence of the first few moments of the absorption signal (i.e. the first few derivatives of the FID at $t = 0$), makes it possible to perform an absolute calibration of the nuclear polarizations. This has still another advantage, resulting from the following properties:

1. By manipulation of equation (13) one can derive a simple relationship between the integral of the absorption signal $-\int_{-\infty}^{+\infty} \langle I_y \rangle (\omega - \omega_0) d\omega$ and the nuclear polarization. The absorption signal thus defined corresponds to a nonsaturating rf field ω_1/γ along Ox in the rotating frame.
2. The ‘absorption’ voltage detected is

$$V(\omega) = \xi \omega_1 \langle I_y \rangle (\omega) \quad (22)$$

where ξ is a factor depending on the coil and on the receiver amplification.

Once one has a calibration of the nuclear polarization, the experimental integral

$$\int V(\omega) d\omega \quad (23)$$

yields a calibration of the product $\xi \omega_1$. Since, as will be seen later, ω_1 can be independently calibrated, we obtain the value of the so-called spectrometer ‘gain factor’ ξ , which can be used to calibrate other physical quantities of interest. This is essential in a domain where everything is highly nonlinear.

Of course, it is equivalent to use the formal expression of the initial FID $\langle I_y \rangle$ following a small-angle pulse and the initial experimentally detected voltage.

3.3 The Moments of the Zeeman Absorption Signal

This section deals only with results, and qualitative comments are made. Detailed calculations can be found in, for example, Abragam et al.¹³ and Roinel and Bouffard.¹⁴

3.3.1 The First Moment

The first moment of the absorption signal (with respect to the Larmor frequency) characterizes the overall shift in the resonance frequency, irrespective of any change in signal shape. The Larmor frequency is determined as the low-polarization limit of the frequency with respect to which the first moment vanishes. One must distinguish between cases when there are one or several spin species.

3.3.1.1 One spin species: the $\frac{3}{2}$ effect. By this we mean nuclear spins with the same chemical shift and the same nuclear environment, e.g. ^{19}F in CaF_2 . Conversely, KMgF_3 contains three imbricated simple cubic arrays of ^{19}F nuclei which, for a given field orientation, differ both in their secular dipolar couplings and in their chemical shifts.¹⁵

For a simple spin species, the first moment is not equal to the average (Weiss) field experienced by the spins of other nuclei, rather it is $\frac{3}{2}$ times larger. This can be illustrated as follows. The secular dipolar interaction experienced by a spin I_i is

$$\mathcal{H}_D^{(i)} = \frac{\gamma^2 \hbar}{2} \sum_j \frac{1 - 3 \cos^2 \theta_{ij}}{r_{ij}^3} \{2I_z^i I_z^j - I_x^i I_x^j - I_y^i I_y^j\} \quad (24)$$

The term inside the braces can be written

$$\{\dots\} = \{2I_z^i \langle I_z^j \rangle + 2I_z^i (I_z^j - \langle I_z^j \rangle) - I_x^i I_x^j - I_y^i I_y^j\} \quad (25)$$

It might seem that the first term on the right-hand side will contribute to the shift of the signal, whereas the remaining terms, corresponding to short-range correlations, affect only the lineshape. This argument is wrong. Indeed, we may write the term in braces in equation (24) in the form

$$\{\dots\} = \{3I_z^i I_z^j - \mathbf{I}^i \cdot \mathbf{I}^j\} \quad (26)$$

The scalar product commutes with

$$I_+ = I_+^i + I_+^j + \sum_{k \neq i, j} I_+^k \quad (27)$$

and it does not contribute to the FID derivative at $t = 0$ (proportional to $\langle [I_+, \mathcal{H}_D] \rangle$). The remaining term is

$$3I_z^i I_z^j = 3I_z^i \langle I_z^j \rangle + 3I_z^i (I_z^j - \langle I_z^j \rangle) \quad (28)$$

The first term on the right-hand side contributes to the first moment, and the second one to the lineshape; thus the ' $\frac{3}{2}$ effect' is recovered. What was wrong with the first reasoning? This was pinpointed by Kittel.¹⁶ We have tacitly assumed in equation (25) that only the longitudinal spin components have nonvanishing average values. In the presence of rf irradiation,

the transverse components no longer vanish, and one should use

$$I_x^i I_x^j = I_x^i \langle I_x^j \rangle + I_x^i (I_x^j - \langle I_x^j \rangle) \quad (29)$$

and similarly for the I_y terms. The Weiss fields originating from these transverse components, however small, are sufficient to account for the $\frac{3}{2}$ effect.

Owing to the long range of the dipolar couplings [equation (24)], the NMR first moment depends on the sample shape. The only case for which the Weiss field is the same for all spins is when the sample is ellipsoid in shape. Otherwise, there is a distribution of Weiss fields, and hence an extra broadening of the line. The case when the first moment vanishes is that of a spherical sample of nuclear spins in cubic symmetry, such as ^{19}F in CaF_2 . It is only when the first moment does not vanish that it can be used for polarization calibration.

3.3.1.2 Several spin species. We consider the case where there are only two species from different nuclear elements, e.g. LiF or LiH . We call the spins I and S . There is no ' $\frac{3}{2}$ effect' between unlike spins, because they precess at different frequencies. The first moments of the two NMR signals are of the form

$$m_{1I} = \frac{3}{2} B_{I \rightarrow I} I p_I + B_{S \rightarrow I} S p_S \quad (30a)$$

$$m_{1S} = B_{I \rightarrow S} I p_I + \frac{3}{2} B_{S \rightarrow S} S p_S \quad (30b)$$

where p_I and p_S are the polarizations.

The various Weiss fields (or their average values in nonellipsoidal samples) can be calculated theoretically. The variation in the moments with the absorption signal areas then yields an absolute calibration of the polarizations. Figure 1 illustrates the use of this method for LiF . The method is easily extended to more than two species.

3.3.2 The Second Moment

Consider the case when the first moment vanishes, for instance that of ^{19}F in a sphere of CaF_2 . The theoretical expression of the second moment is¹³

$$M_2 = \langle [\mathcal{H}_D', I_+] [I_-, \mathcal{H}_D'] \rangle_0 / \langle I_+ I_- \rangle_0 \quad (31)$$

For spins $\frac{1}{2}$, equation (31) yields the following dependence on the nuclear polarization p :

$$M_2(p) = M_2(0)(1 - p^2) \quad (32)$$

One should then observe a linear variation of the experimental M_2 as a function of the square of the signal area.

Figure 2 shows that this is actually the case, for two spherical samples of CaF_2 . The only problem is that the value of M_2 extrapolated to zero polarization is larger than its theoretical value, and different in the two samples. The origin is in the presence of paramagnetic centers at low concentration (Tm^{2+} in the present case), which produce a Lorentzian distribution of fields at the ^{19}F sites.¹³ The two samples have different Tm^{2+} concentrations, and thus different

Figure 1 Experimental first moments (to within an arbitrary constant) of ${}^7\text{Li}$ and ${}^{19}\text{F}$ against their best-fit value in a parallelepiped of LiF . (Reproduced by permission of Oxford University Press from Abragam and Goldman⁴)

Figure 2 Second moment of the ${}^{19}\text{F}$ absorption signal against its area squared (in arbitrary units), for two spherical samples of CaF_2 , with $\mathbf{B}_0 \parallel [100]$. (Reproduced with permission from Abragam et al.¹³)

values of the second-moment excess. This excess depends slightly on nuclear polarization, as derived in Abragam et al.¹³

3.3.3 Higher Moments

These moments also depend on polarization, and could potentially be used for polarization calibration. In particular, for a simple cubic system of spins $\frac{1}{2}$ in a sphere, one predicts for the third moment

$$M_3 \propto p(1 - p^2) \quad (33)$$

which goes through a maximum for $p = 1/\sqrt{3}$. Experimentally, it is extremely difficult to avoid ‘contamination’ of the absorption signal by a small dispersion contribution, whose antisymmetric shape in the wings is sufficient to deprive experimental third moments of any significance.

4 RIGOROUS NMR RESULTS

We list below several results derived theoretically from equation (13). These results are rigorous for systems in the paramagnetic state, that is with an initial density matrix of the form given by equation (1) in an appropriate reference frame. From plausibility arguments, one is inclined to think that many remain valid even in nuclear magnetic ordered states, that is under conditions of symmetry breaking when equation (1) cannot be rigorous.

Each of these results has been implemented experimentally and used as a practical tool for the investigation of spin systems at low temperature. We cite and comment on these investigations, but no detailed calculations are given. We have already described the first investigation, which is concerned with the area of the absorption signal which, after calibration, yields both the polarization and the ‘gain coefficient–rf field’ product $\xi\omega_1$.

4.1 Rate of Change of the Polarization

Consider for simplicity a single-species system subjected to a small rf irradiation at a distance Δ from resonance. Its Hamiltonian in the rotating frame is

$$\mathcal{H} = \Delta I_z + \omega_1 I_x + \mathcal{H}'_D \quad (34)$$

According to the Liouville–von Neumann evolution equation for the density matrix, the rate of change in the longitudinal spin expectation is

$$\begin{aligned} \frac{d}{dt} \langle I_z \rangle &= \text{Tr} \left\{ I_z \frac{d\sigma}{dt} \right\} \\ &= \text{Tr} \{ -i I_z [\mathcal{H}, \sigma] \} \\ &= \text{Tr} \{ -i [I_z, \mathcal{H}] \sigma \} \\ &= \langle -i [I_z, \mathcal{H}] \rangle_0 \end{aligned} \quad (35)$$

and thus, according to equation (34)

$$\frac{d}{dt} \langle I_z \rangle = \omega_1 \langle I_y \rangle \quad (36)$$

If one monitors the absorption signal during an irradiation process, the total change is given by

$$\delta \langle I_z \rangle = \int \omega_1 \langle I_y \rangle dt \quad (37)$$

Use has been made of this method to measure the longitudinal susceptibility in demagnetized spin systems.¹⁷

The basis of the method is as follows. Starting from equilibrium after ADRF, i.e. an initial density matrix

$$\sigma_i = \exp(-\beta_i \hat{\mathcal{H}}'_D) / \text{Tr}\{\dots\} \quad (38)$$

a saturating rf field is suddenly applied at a (small) distance Δ from resonance and one monitors the absorption signal over the course of the evolution of the system towards a new equilibrium of density matrix

$$\sigma_f = \exp[-\beta_f (\mathcal{H}'_D + \Delta I_z + \omega_1 I_x)] / \text{Tr}\{\dots\} \quad (39)$$

If Δ and ω_1 are much smaller than the local field, one has $\beta_f \simeq \beta_i$, and

$$\delta \langle I_z \rangle = \langle I_z \rangle_f = \omega_1 \chi_{\parallel}(\beta) \quad (40)$$

This is measured from the absorption signal using equation (37) and the calibrated value of $\xi \omega_1$.

4.2 Slightly Saturating Linear Passages

We consider a linear sweep of the field (or irradiation frequency) through resonance, with the time of sweep of the linewidth being much longer than T_2 . The irradiation produces a saturation of both the polarization and the dipolar energy, which we presume to be small.

4.2.1 Saturation of the Polarization

Let $d\Delta/dt = \dot{\Delta}$. Equation (37) then yields

$$\delta \langle I_z \rangle = \frac{\omega_1}{\dot{\Delta}} \int_{-\infty}^{+\infty} \langle I_y \rangle(\Delta) d\Delta \quad (41)$$

The limits can be taken equal to $-\infty$ and $+\infty$ if the sweep starts well below resonance and ends well above it. The integral of the absorption signal is precisely related to the value of $\langle I_z \rangle$, which yields

$$\frac{\delta \langle I_z \rangle}{\langle I_z \rangle} = -\epsilon = -\pi \frac{\omega_1^2}{\dot{\Delta}} \quad (42)$$

an expression which is valid for $\epsilon \ll 1$. By performing n passages, one obtains

$$\frac{\langle I_z \rangle(n)}{\langle I_z \rangle(0)} = (1 - \epsilon)^n \simeq \exp(-n\epsilon) \quad (43)$$

through which one measures ϵ . If the sweep rate $\dot{\Delta}$ is known, this provides [from equation (42)] a calibration of ω_1 , that is of the rf field amplitude. An experimental result for CaF_2 is shown in Figure 3. From the calibration of ω_1 , one obtains a calibration of ξ .

4.2.2 Saturation of Dipolar Energy

A Hamiltonian of the form given by equation (34), at constant Δ , is time independent and the energy associated with it is conserved. If ω_1 is strong enough to ensure a single spin

Figure 3 ^{19}F nuclear polarization in CaF_2 as a function of the number of slightly saturating passages. (Reproduced with permission from Abragam et al.¹³)

temperature in the rotating frame but is so small that the energy term $\omega_1 \langle I_x \rangle$ is negligible, one obtains

$$\Delta \langle I_z \rangle + \langle \mathcal{H}'_D \rangle = \text{constant} \quad (44)$$

or

$$\Delta \frac{d}{dt} \langle I_z \rangle + \frac{d}{dt} \langle \mathcal{H}'_D \rangle = 0 \quad (45)$$

which, according to equation (36), gives

$$\frac{d}{dt} \langle \mathcal{H}'_D \rangle = -\omega_1 \Delta \langle I_y \rangle(\Delta) \quad (46)$$

Under a linear passage through resonance, with a frequency sweep rate $\dot{\Delta}$ so slow that equation (46) remains valid at all times, one obtains

$$\delta \langle \mathcal{H}'_D \rangle = -\frac{\omega_1}{\dot{\Delta}} \int_{-\infty}^{+\infty} \Delta \langle I_y \rangle(\Delta) d\Delta \quad (47)$$

a result which is valid only if $\langle \delta \mathcal{H}'_D \rangle$ is small. What can be measured is the dipolar energy variation corresponding to n passages. Provided the product $\xi \omega_1$ is calibrated as explained above, the experimental results can be connected to the high-temperature linear value

$$\langle \mathcal{H}'_D \rangle = -\beta \text{Tr} \mathcal{H}_D^2 \quad (48)$$

and thus one obtains a calibrated value of the energy. It makes use of the (nonnormalized) first moment

$$\mathcal{M}_1 = \int_{-\infty}^{+\infty} \Delta \langle I_y \rangle(\Delta) d\Delta \quad (49)$$

and equation (47) becomes

$$\delta \langle \mathcal{H}'_D \rangle = -\frac{\omega_1}{\Delta} \mathcal{M}_1 \quad (50)$$

This result is independent of whether there are several spin species or not. This method has been used to calibrate the dipolar energy in LiH.¹⁸

4.3 First Moment of the Absorption Signal

We return to the first moment as defined by equation (49). This must not be confused with the normalized first moment described in Section 3.2.1. As the absorption signal $I_y(\Delta)$ is the Fourier transform of the (normalized) FID signal [equation (13)], then

$$\begin{aligned} \Delta \langle I_y \rangle(\Delta) &= \frac{\omega_1}{4} \int_{-\infty}^{+\infty} \langle [I_-, I_+(t)] \rangle_0 \Delta \exp(i\Delta t) dt \\ &= -i \frac{\omega_1}{4} \int_{-\infty}^{+\infty} \langle [I_-, I_+(t)] \rangle_0 \frac{d}{dt} [\exp(i\Delta t)] dt \end{aligned} \quad (51)$$

Upon integration by parts over t , and then integration over Δ , one obtains finally¹⁹

$$\mathcal{M}_1 = \frac{\pi}{2} \omega_1 \langle [I_-, [I_+, \mathcal{H}'_D]] \rangle_0 \quad (52)$$

The simplest case is when the system contains only one spin species. Through the commutation relations of spin operators, and the form [equation (24)] of the homonuclear secular dipolar interactions, one obtains

$$\mathcal{M}_1 = 3\pi\omega_1 \langle \mathcal{H}'_D \rangle_0 \quad (53)$$

What is actually measured is

$$\mathcal{M}'_1 = \xi \mathcal{M}_1 = 3\pi\xi\omega_1 \langle \mathcal{H}'_D \rangle_0 \quad (54)$$

The calibration of $\xi\omega_1$ then gives access to a calibrated value of $\langle \mathcal{H}'_D \rangle$.

Consider now the case when there are, say, two spin species I and S . Secular dipolar interactions between unlike spins do not contain flip-flop terms, and it is elementary to show that in such a case

$$\mathcal{M}_1(I) = \pi\omega_1^I \{3\langle \mathcal{H}'_{DII} \rangle_0 + \langle \mathcal{H}'_{DIS} \rangle_0\} \quad (55)$$

and for the spins S signal

$$\mathcal{M}_1(S) = \pi\omega_1^S \{\langle \mathcal{H}'_{DIS} \rangle_0 + 3\langle \mathcal{H}'_{DSS} \rangle_0\} \quad (56)$$

Together with the measurement of the total dipolar energy

$$\langle \mathcal{H}'_{DII} \rangle_0 + \langle \mathcal{H}'_{DIS} \rangle_0 + \langle \mathcal{H}'_{DSS} \rangle_0 \quad (57)$$

by using the saturation method described in the preceding section, it is possible in principle to derive calibrated values for the three partial energies

$$\langle \mathcal{H}'_{DII} \rangle_0, \quad \langle \mathcal{H}'_{DIS} \rangle_0, \quad \langle \mathcal{H}'_{DSS} \rangle_0 \quad (58)$$

4.4 Qualitative Shape of the Absorption Signal

When a spin system, with a single spin species I (for simplicity), is subjected to an ADRF stopped at the distance Δ_0 from resonance, its density matrix is of the form

$$\sigma = \exp[-\beta(\Delta_0 I_z + \mathcal{H}'_D)] / \text{Tr}\{\exp(\dots)\}$$

We assume that $\beta > 0$. If one then looks at the absorption signal $I_y(\Delta)$ with a small, nonsaturating rf field, it can be shown (see Abragam and Goldman,⁶ Chapter 5), that this absorption signal is positive for $\Delta \leq \Delta_0$, vanishes at $\Delta = \Delta_0$, and is negative for $\Delta \geq \Delta_0$. This makes it possible to determine the value of Δ_0 in equation (58), that is the effective field. In the particular case when $\Delta_0 = 0$, it can be shown that the absorption signal is antisymmetric at all spin temperatures

$$\langle I_y \rangle(-\Delta) = -\langle I_y \rangle(\Delta) \quad (59)$$

4.5 Linear Response and Transverse Susceptibility

The transverse susceptibility can be defined through two seemingly different approaches:

1. We wait for the thermal equilibrium when a small (but saturating) rf field is applied at a distance Δ_0 from resonance. This corresponds to a density matrix

$$\sigma_{\text{eq}} = \exp[-\beta(\Delta_0 I_z + \omega_1 I_x + \mathcal{H}'_D)] / \text{Tr}\{\dots\} \quad (60)$$

which yields a transverse spin expectation value

$$\langle I_x \rangle_{\text{eq}} = \chi_{\perp} \omega_1 \quad (61)$$

2. Starting from a density matrix

$$\sigma_{\text{eq}} = \exp[-\beta(\Delta_0 I_z + \mathcal{H}'_D)] / \text{Tr}\{\dots\} \quad (62)$$

we apply a small rf field of amplitude ω_1/γ and look for the dispersion signal at frequency Δ_0

$$\langle I_x \rangle(\Delta_0) = \chi'_{\perp} \omega_1 \quad (63)$$

It can be shown, on the basis of linear response theory, that the two transverse susceptibilities are equal

$$\chi_{\perp} = \chi'_{\perp} \quad (64)$$

The former definition corresponds to the observation of dispersion during a fast passage (slow enough for the system to be at all times infinitely close to equilibrium, but fast enough for spin–lattice relaxation to be negligible). For the second definition, it is not necessary to look at the dispersion signal.

Instead, one can observe the absorption signal $\langle I_y \rangle(\Delta)$ and compute the dispersion $\langle I_x \rangle(\Delta_0)$ from the Kramers–Kronig relation¹

$$\langle I_x \rangle(\Delta_0) = -\frac{1}{\pi} \mathcal{P} \int_{-\infty}^{+\infty} \frac{\langle I_y \rangle(\Delta) d\Delta}{\Delta - \Delta_0} \quad (65)$$

Since the absorption signal is calibrated, as shown above, this method yields a calibrated value for the transverse susceptibility.

4.6 Cotanh Transform of the Absorption Signal: Measurement of the Dipolar Temperature

The cotanh transform is one form of the fluctuation–dissipation theorem,²⁰ as applied to the absorption signal.¹⁸ For a system demagnetized to the distance Δ_0 from the spins I resonance, i.e. for a single spin system, when its density matrix is of the form given by equation (62), the cotanh transform (a neologism) is formally defined by

$$\mathcal{C}(\beta) = \int_{-\infty}^{+\infty} \langle I_y \rangle(\Delta) \coth \left[\frac{\beta}{2} (\Delta - \Delta_0) \right] d\Delta \quad (66)$$

where $\langle I_y \rangle(\Delta)$ is the absorption signal.

It can be shown that

$$\mathcal{C}(\beta) = -\pi \omega_1 \langle I_x^2 + I_y^2 \rangle_0 \quad (67)$$

This property is valid even when there are several spin species. It can be used when, besides the abundant spins, the system also contains a spin species in low abundance (for instance ^{43}Ca in CaF_2). It is these spins that we call I . Since, for example,

$$I_x = \sum_i I_x^i \quad (68)$$

is the sum of all individual spin components, we have

$$\langle I_x^2 \rangle_0 = \sum_i \langle I_x^{i2} \rangle_0 + \sum_{i \neq j} \langle I_x^i I_x^j \rangle_0 \quad (69)$$

For low-abundance spins, their relative distance is large, on average, so that

$$\langle I_x^i I_x^j \rangle_0 \simeq \langle I_x^i \rangle_0 \langle I_x^j \rangle_0 \quad (i \neq j) \quad (70)$$

which vanishes when the spins I are not purposely given a transverse polarization. One is then left with

$$\langle I_x^2 \rangle_0 + \langle I_y^2 \rangle_0 \simeq \sum_i \langle I_x^{i2} + I_y^{i2} \rangle_0 = \sum_i [I(I+1) - \langle I_z^{i2} \rangle_0] \quad (71)$$

In the presence of N_I equivalent spins I , one then has

$$\mathcal{C}(\beta) = -N_I \pi \omega_1 [I(I+1) - \langle I_z^2 \rangle_0] \quad (72)$$

In the case when nuclear alignment is negligible

$$\langle I_z^2 \rangle_0 = \frac{1}{3} I(I+1) \quad (73)$$

and one finally obtains

$$\mathcal{C}(\beta) \simeq -\frac{2}{3} N_I \pi \omega_1 I(I+1) \quad (74)$$

Using calibrated absorption signals, one adjusts by trial-and-error the value of β in equation (66) so as to satisfy equation (74). This yields a calibrated value of the spin temperature β^{-1} .

5 NONLINEAR EFFECTS IN SPIN TEMPERATURE

Consider, for simplicity, a system with only one spin species, subjected to Zeeman and dipolar interactions. At high field, there are two constants of the motion: the Zeeman energy $\omega_0 I_z$ and the secular dipolar energy $\langle \mathcal{H}'_D \rangle$. Internal equilibrium corresponds to the most probable state, i.e. that which maximizes the entropy

$$S = -k_B \text{Tr}\{\sigma \ln \sigma\} \quad (75)$$

where σ is the spin density matrix, and is consistent with the conservation of the above-mentioned quantities. This corresponds to a density matrix of the form

$$\sigma = \exp(-\beta_Z \omega_0 I_z - \beta \mathcal{H}'_D) / \text{Tr}\{\exp(\dots)\} \quad (76)$$

where β_Z and β are the Zeeman and dipolar inverse temperatures, respectively. If we introduce the partition function

$$\mathcal{Z}(\beta_Z, \beta) = \text{Tr}\{\exp(-\beta_Z \omega_0 I_z - \beta \mathcal{H}'_D)\} \quad (77)$$

we have

$$\omega_0 \langle I_z \rangle = \omega_0 \text{Tr}\{\sigma I_z\} = -\frac{\partial}{\partial \beta_Z} \ln \mathcal{Z} \quad (78)$$

$$\langle \mathcal{H}'_D \rangle = \text{Tr}\{\sigma \mathcal{H}'_D\} = -\frac{\partial}{\partial \beta} \ln \mathcal{Z} \quad (79)$$

At high temperature, that is to first order with respect to the inverse spin temperature, one obtains the well-known result

$$\omega_0 \langle I_z \rangle = -\beta_Z \omega_0^2 \text{Tr}\{I_z^2\} \quad (80a)$$

$$\langle \mathcal{H}'_D \rangle = -\beta \text{Tr}\{\mathcal{H}'_D^2\} \quad (80b)$$

At lower temperature, both $\omega_0 \langle I_z \rangle$ and $\langle \mathcal{H}'_D \rangle$ depend, in a complicated way, on both inverse temperatures, β_Z and β . All the problems arise from the term in $\mathcal{H}'_D$. If β is zero, that is there is purely Zeeman order, it is elementary to calculate all steady-state expectation values of interest (as seen above, calculating a dynamic quantity such as the FID remains a formidable task). We describe a perturbative approach in which one calculates the physical quantities to all orders with respect

to the inverse Zeeman temperature β_Z , but in the form of a power expansion in dipolar inverse temperature β (it will be shown that, in fact, we can achieve slightly more than that). For secular dipolar interactions, and especially for spins $\frac{1}{2}$, the most convenient approach is through the diagrammatic method devised by Stinchcombe et al.^{21,22} The method is not described in detail here. Suffice it to say that the diagram contains bonds, associated with dipolar interaction coefficients, and vertices, the values of which depend on the inverse Zeeman temperature. More precisely, for spins $\frac{1}{2}$, the values depend on

$$t = \tanh(-\frac{1}{2}\beta_Z\omega_0) \quad (81)$$

By differentiating equations (78) and (79) with respect to β and with respect to β_Z , respectively, we obtain

$$\frac{\partial}{\partial\beta}\omega_0\langle I_z \rangle = \frac{\partial}{\partial\beta_Z}\langle \mathcal{H}'_D \rangle \quad (82)$$

whence

$$\omega_0\langle I_z \rangle(\beta_Z, \beta) = \omega_0\langle I_z \rangle(\beta_Z, 0) + \int_0^\beta \frac{\partial}{\partial\beta_Z}\langle \mathcal{H}'_D \rangle(\beta_Z, \lambda) d\lambda \quad (83)$$

This enables one to calculate $\langle I_z \rangle$ as a power expansion in β from the corresponding expansion for $\langle \mathcal{H}'_D \rangle$. One can also obtain β -expansion formulas for the entropy, free energy, etc.

There is an advantage in using this approach for systems where the spins experience a longitudinal average field, that is when, in equation (24)

$$\frac{\gamma^2\hbar}{2} \sum_j \frac{1 - 3\cos^2\theta_{ij}}{r_{ij}^3} = q \neq 0 \quad (84)$$

a value which is equal for all spins i .

It can be proved that, in such a case, all vertices can be 'renormalized' in such a way that:

1. one considers only diagrams with no free ends; and
2. in each vertex, the term t in equation (81) is replaced by

$$t' = \tanh(-\frac{1}{2}\beta_Z\omega_0 - \frac{1}{2}\beta qt) \quad (85)$$

For a given physical quantity, the term of zero order corresponds to the mean-field approximation, and the terms in increasing powers of β correspond to the contributions of short-range correlations of increasing order.

We present below several experimental illustrations of nonlinear effects in spin temperature, for ^{19}F spins in spherical samples of CaF_2 ($q = 0$), together with the theoretical predictions from expansions up to β^3 .

5.1 Dipolar Energy versus Polarization in High Effective Field

The experiment consists of measuring $\langle \mathcal{H}'_D \rangle$ as a function of polarization p in a system having a density matrix

$$\sigma = \exp[-\beta(\Delta_0 I_z + \mathcal{H}'_D)] / \text{Tr}\{\dots\} \quad (86)$$

Figure 4 Non-Zeeman energy per fluorine spin as a function of nuclear polarization, in a spherical sample of CaF_2 at thermal equilibrium in the rotating frame in an effective field of 7.12 G· $\mathbf{B}_0 \parallel [100]$ and $T > 0$. Curves 1 and 2: first- and third-order approximations with dipolar interactions only. Curve 3: after addition of an adjusted contribution from impurities. (Reproduced with permission from Goldman et al.²³)

Figure 5 Transverse susceptibility of ^{19}F in a spherical sample of CaF_2 in zero effective field, against dipolar energy, together with first- and third-order approximations. Conditions: $\mathbf{B}_0 \parallel [100]$, $T < 0$. (Reproduced with permission from Goldman et al.²³)

in the case when Δ_0 is much larger than the local frequency D . When limited to the first order in β , the theoretical expression is

$$\langle \mathcal{H}'_D \rangle = \frac{N}{4} \frac{D^2}{\Delta_0} \ln \left(\frac{1+p}{1-p} \right) \times (1-p^2) \left(1 - \frac{2}{3} p^2 \right) \quad (87)$$

where β is expressed as a function of p .

Figure 6 Longitudinal susceptibility of ^{19}F in the same sample and under the same conditions as in Figure 5. (Reproduced with permission from Goldman et al.²³)

Experimentally, one measures the loss of polarization resulting from a sudden rf irradiation at Δ_0 from resonance, starting from a state of pure Zeeman order. Figure 4 shows that agreement with theory requires the addition of an extra term to the secular dipolar reservoir.²³ The extra term has been identified as originating in the random field distribution due to the presence of paramagnetic impurities.

5.2 Transverse and Longitudinal Susceptibilities

Figures 5 and 6 show the transverse and longitudinal susceptibilities in zero effective field as a function of the dipolar energy,²³ together with the theoretical expectation from expansions up to β^3 . The experimental method²³ used to obtain these two figures is rather complicated and is not described here. As can be seen in Figures 5 and 6, the results depart markedly from theory at dipolar energies per spin above about 2 kHz. This is no accident: these experiments were part of a general study of nuclear magnetic ordering and, as confirmed by other observations, the departures coincide with the onset of nuclear antiferromagnetism—but that is another story.

1 INTRODUCTION

In the context of this article, the term ‘optical pumping’ refers to the creation of large, nonequilibrium nuclear spin polarizations by irradiation of a sample at optical wavelengths. Significant optical pumping effects have been reported in several classes of samples, including organic molecular crystals,¹ mixtures of noble gases and alkali metal vapors,² biological photosynthetic systems,^{3–5} and inorganic semiconductors.^{6,7} Optical pumping of nuclear spin polarization in a semiconductor was first described by George Lampel in 1968, for the case of crystalline Si.⁶ In Lampel’s original experiments, Si samples were irradiated with an arc lamp at 77 K and fields of 0.16 T or less, and ²⁹Si polarization was measured by direct NMR detection. Optical pumping was observed with both circularly polarized and unpolarized light. Lampel’s observations were explained in terms of photoexcitation of conduction electrons with nonequilibrium electron spin polarization and subsequent dynamic polarization of hyperfine-coupled nuclear spins. Although the magnitude of the ²⁹Si polarizations in Lampel’s experiments were only of order 10^{–5}, these experiments set the stage for later optical pumping experiments in which polarizations of order 10% have been achieved.^{8,9}

Following Lampel’s experiments and other optical pumping experiments on Si,^{10–12} attention shifted to III–V semiconductors, principally GaAs and AlGaAs, and to optical detection

of the NMR spectra.^{13–17} These and other recent experiments have been performed at temperatures on the order of 10 K or lower. In optically detected NMR (ODNMR) experiments, the large nuclear spin polarization created by optical pumping exerts a strong average hyperfine field on the photoexcited electrons, which can then affect the evolution or steady-state of the photoexcited electron spin polarization. In analogy to the Hanle effect,^{18,19} the optically pumped nuclear hyperfine field can be made to reduce the degree of circular polarization of the photoluminescence that accompanies electron-hole recombination when radio-frequency (rf) fields are applied near the NMR lines. The original ODNMR experiments on semiconductors^{13–17} were carried out on bulk materials and with continuous wave (cw) rf irradiation (i.e., frequency domain ODNMR). Recent ODNMR experiments have focussed on semiconductor thin films and heterostructures^{20–23} and on the development of time-domain variants that lead to dramatic improvements in NMR resolution.^{9,24,25} Simultaneously, there has been a revival of interest in directly detected, optically pumped NMR (OPNMR).^{8,26–33} OPNMR measurements with direct detection have been used to investigate the properties of quantum confined conduction electrons in two-dimensional systems at low temperatures and high fields,^{34–38} a topic of considerable interest to condensed matter physicists.^{39–41} Notably, OPNMR measurements have provided the first evidence for and characterization of novel electron states called skyrmions in two-dimensional electron systems (2DES).^{34,35}

2 DIRECTLY DETECTED VS. OPTICALLY DETECTED

An important advantage of both time-domain and frequency-domain ODNMR methods is their extremely high sensitivity. Because of the high efficiency for detection of optical photons, it is possible in principle to detect the NMR spectrum of nuclei in the vicinity of single luminescent defect or impurity site in a semiconductor sample, comprising roughly 10⁵ nuclei. In fact, ODNMR spectra of single GaAs quantum dots containing approximately this number of nuclei have been reported,^{42–44} although in these experiments the NMR spectra were detected through modulation of the photoluminescence energy, rather than polarization, by manipulation of the optically pumped nuclear polarization. In ODNMR experiments in which photoluminescence polarization was monitored, NMR spectra of less than 10¹¹ nuclei have been detected.^{16,21}

An apparent limitation on ODNMR techniques based on photoluminescence polarization is that they can only be applied when the nuclear hyperfine field is a significant fraction of the external magnetic field. In practice, such ODNMR experiments are typically performed at magnetic field strengths below 1 T.

Advantageous features of directly detected OPNMR include: (1) compatibility with high fields (to the extent that the optical pumping effect itself occurs at high field);^{31,33} (2) absence of photoluminescence requirements; (3) ability to detect NMR spectra of both the ground state and the photoexcited state of the sample; (4) ability to detect NMR spectra of sample regions that are spatially distinct from the optically absorbing regions, through nuclear spin diffusion;^{34,35}

(5) full compatibility with pulsed NMR methodology, including multiple pulse line-narrowing techniques, heteronuclear decoupling, multidimensional spectroscopy, and nuclear spin relaxation measurements. Some of these advantages are shared by time-domain or time-sequenced ODNMR techniques.^{9,24,25} In principle, because optical pumping can produce nuclear spin polarizations of order 10%,^{8,9} the sensitivity of directly detected OPNMR is sufficient for the observation of roughly 10^{14} nuclei (with signal averaging), or the number of nuclei in a semiconductor monolayer with a surface area of approximately 0.2 cm^2 .

Examples of OPNMR spectra of bulk GaAs and InP are shown in Figures 1 and 2. Spectra of semiconductor quantum well samples are discussed in Section 4.

Very recently, all-optical NMR experiments on semiconductors, i.e., experiments in which nuclear spin transitions are

detected with only optical irradiation of a sample, have been reported.^{45–47} In these experiments, a near-infrared pump laser tuned near the semiconductor absorption band edge and propagating in a direction not parallel to the applied static magnetic field is pulsed^{45,46} or modulated in amplitude or phase⁴⁷ at radio frequencies, but no rf irradiation or pulses are applied. A plot of the Faraday rotation of a weaker probe laser^{45,46} or of photoluminescence polarization⁴⁷ versus the modulation frequency of the pump laser shows discontinuities at the NMR frequencies. Such experiments have been reported both for bulk GaAs^{45,46} and for GaAs quantum wells.^{46,47} Both single-quantum ($|\Delta m| = 1$) and overtone ($|\Delta m| = 2$) NMR transitions have been detected. Single-quantum transitions are attributed to modulation of electron-nucleus magnetic hyperfine couplings at the laser modulation frequency,^{45–47} while overtone transitions are attributed to modulation of nuclear electric quadrupole couplings at the laser modulation frequency.^{46,47} Observation of both types of NMR transitions is dependent upon optical pumping of nuclear spin polarizations away from resonance and subsequent destruction of the nuclear spin polarization at the resonant conditions. Further exploration and exploitation of all-optical NMR effects in semiconductors, and possibly other materials, is likely in the near future.

3 MECHANISM OF OPTICAL PUMPING

The general features of the physical mechanism of optical pumping in semiconductors have been described.⁷ Briefly, photoexcitation of a direct-gap, ZnS-structure, bulk semiconductor at the band edge (Γ point) in zero magnetic field creates conduction electrons with spin polarization $\langle S_z \rangle = \pm(1/4)\sigma$, where the light helicity σ is +1 for left-circular-polarized light, -1 for right-circular-polarized light, and 0 for unpolarized light. Provided that the spin-lattice relaxation time of photoexcited electrons is not much less than the photoexcitation lifetime, a net nonequilibrium electron spin polarization is created. The electrons couple to nuclei by Fermi contact hyperfine interactions. If the hyperfine interactions fluctuate with a sufficiently short correlation time, flip-flop transitions efficiently transfer electron spin polarization to the nuclei. At steady state, the nuclear spin temperature T_n is related to the electron spin temperature T_e and lattice temperature T by the expression $(T_n^{-1} - T^{-1}) = \gamma_e/\gamma_n(T^{-1} - T_e^{-1})$, where γ_e and γ_n are the electronic and nuclear magnetogyric ratios. Since $\gamma_e/\gamma_n \sim 10^3$, a small deviation of the electron spin polarization from thermal equilibrium produces a very low (positive or negative) nuclear spin temperature, i.e., a large nuclear spin polarization.

It is commonly assumed that optical pumping is driven primarily by localized electron states (e.g., electrons trapped at defect or shallow donor sites), rather than delocalized, Bloch-function states. This is because the rate of flip-flop transitions depends on the square of the hyperfine couplings, and therefore on the square of the electron probability density at the nuclei. Because the total electron probability density (not squared) is normalized, electron states that concentrate the probability density in a smaller volume can produce a greater net flip-flop rate.

Despite this general understanding of optical pumping, nearly all details of the mechanism remain mysterious. For example:

Figure 1 Optically pumped ^{71}Ga NMR spectra of a semi-insulating GaAs wafer at 4.3 K in a 9.39-T field, obtained with an optical pumping time of 10 s, a photon energy of 1.49 eV (831 nm wavelength), and the indicated light polarizations. The laser power was 240 mW in a 5-mm diameter spot. Emissive OPNMR signals are observed with linear and $\sigma+$ polarization. Under the conditions of these experiments, the optically pumped nuclear spin polarizations are of order 1%, but larger polarizations are created with longer pumping times. No NMR signals are detectable when the laser light is blocked, because of both the smaller nuclear spin polarization at equilibrium and the very long spin-lattice relaxation times in the dark ($>10^3$ s). Quadrupole splittings of the NMR lines arise from strain due to thermal contraction of the GaAs wafer, which was glued to a sapphire block in the low-temperature NMR probe

Figure 2 Optically pumped ^{31}P NMR spectra of a 348- μm thick Fe-doped semi-insulating InP wafer at 6 K, obtained in a superconducting magnet with a central field of 9.39 T. The InP wafer was located outside the homogeneous region of the magnet, producing a strong field gradient perpendicular to the surface of the wafer. The spectra then represent one-dimensional images of the nuclear spin polarization.⁸ (a) Low resolution images. The InP wafer is situated in a 0.195 T/cm gradient, with an optical pumping time of 600 s at 1.412 eV, or 878 nm wavelength. Spectra were obtained with $\sigma+$ and $\sigma-$ polarized light, at a power of 200 mW in a 3.7-mm diameter spot, and in the dark. The wafer thickness corresponds to an NMR frequency range of 116 kHz. With optical pumping, ^{31}P nuclei near the laser-irradiated surface acquire either positive or negative nonequilibrium spin polarizations, depending on the direction of light polarization. (b) High resolution images. The InP wafer is situated in a 0.453 T/cm gradient, with an optical pumping time of 120 s at the indicated photon energies. Spectra were obtained with $\sigma+$ polarized light, at a power of 25 mW in a 0.45-mm diameter spot. Vertical axis is reversed relative to (a). The absorption band edge for InP at low temperatures occurs at approximately 1.427 eV, where the light penetration depth is approximately 2 μm . As the laser is tuned to lower energies, the pumping light penetrates deeper into the wafer, producing an asymmetrically broadened ^{31}P NMR lineshape. A 2- μm distance corresponds to an NMR frequency shift of 1.6 kHz. (Adapted from Ref.⁸)

1. The identity of the localized states that produce optical pumping is not firmly established in any specific sample, either bulk or heterostructure.
2. The source of hyperfine fluctuations has not yet been identified conclusively. The classic Overhauser effect in a *metal* depends on hyperfine fluctuations due to translational motion of delocalized electrons near the Fermi surface. In optically pumped semiconductors, this contribution is considered negligible. Recent studies of the field dependence of optical pumping in GaAs and InP suggest that the relevant fluctuations have time scales of order 10 ps.^{31,33,48}
3. Possible effects of high fields on the band structure, optical selection rules, electron-hole pairing and localization, or other aspects of the photophysics relevant to optical pumping have not been explored in theory or experiment.
4. Possible contributions to the optical pumping process from hyperfine couplings to photoexcited valence band holes and effects of spin-selective electron-hole recombination⁴⁹ on the electron spin polarization have not been analyzed in detail.
5. The signs of optically pumped ^{31}P polarizations in undoped InP^{27,33} (but not Fe-doped, semi-insulating InP^{8,28}) have been found to be opposite to expectations based on the simple theory outlined above, i.e., $\sigma-$ and linearly polarized light produce negative ^{31}P polarization, while $\sigma+$ light produces positive polarization. In GaAs, the signs of optically pumped nuclear spin polarizations are in accord with expectations.
6. The dependences of nuclear spin polarization on the optical photon energy in bulk GaAs and InP are not well understood. In bulk GaAs, a strong maximum in the nuclear spin polarization is observed at photon energies approximately 20 meV below the band edge, and little or no polarization is created at higher energies.²⁹ This observation has been attributed tentatively to direct pumping of shallow traps or excitons.²⁹ In bulk InP, a similar maximum has been shown by stray-field NMR imaging to be due primarily to the increased optical absorption length (i.e., greater optically pumped volume) below the band edge.⁸ In bulk InP, substantial nuclear spin polarizations are generated with photon energies up to at least 60 meV above the band edge.^{8,27}
7. In GaAs/AlGaAs quantum well samples at high field, optical pumping effects saturate at very low photon flux,²⁶ of order 60 mW cm⁻², while photoluminescence does not saturate up to at least 3 W cm⁻². This observation suggests a ‘phase-space filling’ phenomenon in which a rather

low density of photoexcitations is sufficient to occupy all electronic states that play a role in optical pumping.

8. Recent OPNMR experiments on bulk InP have revealed that optical pumping creates nuclear spin dipolar order in addition to the Zeeman order predicted by the simple theory outlined above.²⁸ Possible explanations for optical pumping of dipolar order include direct generation through electron-nuclear cross relaxation, dependent on dipolar hyperfine interactions and nuclear dipole-dipole couplings,⁵⁰ and indirect generation through diffusion of Zeeman order in the presence of spatial gradients of NMR frequencies.²⁸ The dominant mechanism for optical pumping of dipolar order has not been established experimentally.

Obviously, there is a great deal of room for further research into the fundamental aspects of optical pumping in semiconductors. Nonetheless, even in the absence of a detailed understanding of the mechanism, the optical pumping effect can be useful both for sensitivity enhancement and for spatial localization of NMR signals. The utility of optical pumping is exemplified by OPNMR studies of 2DES in GaAs/AlGaAs quantum wells, as described below.

4 APPLICATION TO TWO-DIMENSIONAL ELECTRON SYSTEMS IN THE QUANTUM HALL REGIME

A 2DES, cooled to extremely low temperatures in a strong magnetic field, exhibits many exotic phenomena, including the integer⁵¹ and fractional⁵² quantum Hall effects that are the subject of a large body of experimental and theoretical studies by condensed matter physicists. Transport and optical studies of the 2DES have shown that the low-energy physics in these extreme conditions is driven by the electron-electron Coulomb interaction,⁵³ making this ‘simple’ system one of the hardest to understand theoretically. OPNMR studies have contributed to the recent progress on this problem by providing important new insights into the electron spin degree of freedom, which helps to shed light on the low-lying many-body states that exist in a real 2DES.^{39–41}

For these OPNMR experiments, samples typically contain multiple copies (up to forty) of a fundamental unit: a GaAs quantum well (i.e., a GaAs layer approximately 300 Å thick) doped with electrons ($n \sim 1 \times 10^{11} \text{ cm}^{-2}$), sandwiched between $\text{Al}_{0.1}\text{Ga}_{0.9}\text{As}$ barriers (i.e., $\text{Al}_{0.1}\text{Ga}_{0.9}\text{As}$ layers approximately 1500 Å thick).^{54–56} At low temperatures, all conduction electrons are confined to the quantum wells and are in the same ‘2D state’ (i.e., the lowest electronic subband of the well). The normal component of a strong magnetic field ($B \cos \theta$, where θ is the angle between the external field $\mathbf{B}$ and the direction normal to the plane of the quantum well) quantizes the 2D motion into spin-split Landau levels.^{54,55} In this regime, the many-body states and thus the physical properties of the 2DES are determined by the Landau level filling factor $\nu = (nhc/eB \cos \theta)$, where h , c , and e are Planck’s constant, the velocity of light, and the electron charge. By varying n , B , or θ , ν may be tuned to reach integral⁵¹ (e.g., $\nu = 1$) or fractional⁵² (e.g., $\nu = 1/3$) quantum Hall ground states.^{39–41,53} These are states in which the longitudinal resistivity ρ_{xx} of the 2DES vanishes and the transverse (or Hall) resistivity ρ_{xy} plateaus at the values $(hc/\nu e^2)$. In OPNMR experiments on

2DES in GaAs quantum wells,^{34–38,57,58} ν is varied for a sample with given n by varying θ and by performing experiments at several values of B .

Figure 3 shows ^{71}Ga OPNMR spectra of a multiple quantum well sample, acquired using the timing sequence SAT – τ_L – τ_D – DET.^{26,34,35,57} SAT represents an rf pulse train that saturates nuclear spin polarization. During τ_L , a near-infrared laser optically pumps the quantum well, using a photon energy above the band edge of the well and below that of the barrier. Because the laser is tuned to be absorbed only in the quantum well layers, only nuclear spins in the quantum wells, and not in the barrier, become strongly polarized. The enhanced NMR signal observed after a short illumination period (e.g., $\tau_L \sim 5 \text{ s}$) is due to nuclei in the quantum wells (‘W’ signals in Figure 3). Eventually (e.g., as $\tau_L \rightarrow 200 \text{ s}$), the optically pumped nuclear polarization spreads into the barrier regions

Figure 3 ^{71}Ga NMR lineshapes of an optically pumped GaAs multiple quantum well sample, obtained in a 12 T field at the indicated temperatures.³⁷ (a) Spectrum at Landau level filling factor $\nu = 1/3$ after approximately 60 s of optical pumping. Peak labeled W arises from nuclei in the 26-nm thick GaAs wells. Peak labeled B arises from the 312-nm thick $\text{Al}_{0.1}\text{Ga}_{0.9}\text{As}$ barriers between wells. The Knight shift K_S is defined empirically as the splitting between the peaks. The shaded lineshape is a simulation of the intrinsic Knight shift lineshape, with maximum shift $K_{S,\text{int}}$. The dashed line is a fit to the experimental lineshape obtained by convoluting the intrinsic lineshape with a Gaussian lineshape attributable to nuclear magnetic dipole-dipole couplings. (b) Temperature dependence of the optically pumped ^{71}Ga NMR lineshape at $\nu = 0.267$. (Reprinted from Ref.³⁷)

by nuclear spin diffusion. A second NMR signal due to nuclei in the barriers then appears ('B' signals in Figure 3). After a period τ_D in the dark ($\tau_D \geq 1$ s), nuclear free induction decay signals are recorded in the period DET. These signals probe the equilibrium properties of the 2DES as functions of ν and temperature. Nuclear spin-lattice relaxation rates R_1 at thermal equilibrium can be determined from the dependence of OPNMR signal amplitudes on τ_D^{35} .

The Knight shift (K_S) of quantum well signals may be defined^{26,34,35} as the peak-to-peak splitting between quantum well and barrier signals (see Figure 3). K_S is due to Fermi contact hyperfine couplings between nuclei and doped (not photoexcited, because the OPNMR signals are observed in the dark after τ_D) conduction electrons confined in the quantum wells and is proportional to the spin polarization of the 2DES. The temperature dependence of K_S [Figure 3(b)] reveals the increasing spin polarization of the electrons³⁶ as they are cooled into a ferromagnetic ground state⁵⁹ [see Figure 4(a)]. As shown in Figure 3(a) (dashed line), a more quantitative determination of K_S^{37} is achieved by fitting the experimental OPNMR lineshape to the convolution of the intrinsic hyperfine lineshape of the well and barrier [Figure 3(a), shaded] with a 3.5 kHz FWHM Gaussian lineshape due to nuclear magnetic dipole-dipole couplings. The central assumption of this model of the lineshape is that nuclei in the quantum well experience a hyperfine magnetic field that scales with the electron probability density in the direction perpendicular to the plane of the well but is uniform in the plane of the well. This model requires that any reversed electron spins [e.g., thermally excited spin waves, see Figure 4(b)] are delocalized within the plane of the quantum well, such that the electron spin polarization appears spatially homogeneous when averaged over the time scale of the NMR experiment, which is of order 40 μ s. Simulated OPNMR lineshapes in this motionally-narrowed limit fit the experimental spectra at $\nu = 1/3$ and $\nu = 1$ over the observed temperature range.

The experimentally determined $K_S(T, \nu)$ represents a direct and calibrated measure^{34,36} of the 2DES spin polarization $P(T, \nu) \equiv \langle S_z(T, \nu) \rangle / \max(S_z)$. Figure 5 shows $P(T, \nu)$ measured by OPNMR at three important filling factors, $\nu = 1$,⁶⁰ $\nu = 1/3$,³⁶ and $\nu = 1/2$.³⁸ Both the $\nu = 1$ and the $\nu = 1/3$ electronic states become fully polarized in the low temperature limit [see Figure 4(a)], in agreement with theoretical predictions^{59,61–63} that these integer and fractional ground states are quantum Hall ferromagnets (QHFM). $P(T, \nu)$ decreases with increasing temperature due to thermally excited spin-waves [see Figure 4(b)]. Data at $\nu = 1$ were obtained at $B \approx 7$ T, where the electron Zeeman energy corresponds to a temperature $T_Z \approx 2.1$ K, whereas data at $\nu = 1/3$ were obtained at $B \approx 12$ T, where $T_Z \approx 3.5$ K. The more rapid drop-off of $P(T, \nu = 1/3)$ shows the dominant role that the electron-electron Coulomb interaction plays in the spectrum of excited states.⁶¹ Specifically, the 'spin stiffness' at $\nu = 1$ is expected⁶⁴ to be much higher than at $\nu = 1/3$, which means that the number of spin waves present at low temperature is much less for $\nu = 1$, consistent with the data (Figure 5). OPNMR measurements of $P(T, \nu = 1)$ have stimulated additional progress on the theoretical description of QHFM,^{65–68} since the conventional assumption of dilute spin waves can not describe the experiments once the temperature exceeds T_Z .

Figure 5 also shows OPNMR measurements of $P(T, \nu = 1/2)$, which appear to indicate a partially polarized 2DES

Figure 4 Illustration of electronic states in a two-dimensional system at low temperatures and high magnetic fields, as for conduction electrons in a OPNMR experiments on GaAs quantum wells. (a) At very low temperatures and Landau level filling factor $\nu = 1$, the electrons fill the lowest state of translational energy with maximum spin polarization, producing the maximum Knight shift in an OPNMR measurement. (b) At somewhat higher temperatures, thermally excited electron spin waves reduce the electron spin polarization, thereby reducing the Knight shift. (c) At very low temperatures and filling factors slightly above one, additional electrons must occupy spin-reversed states. Electron-electron interaction energies are minimized by tilting the spins of neighboring electrons, resulting in a more rapid destruction of the electron spin polarization and Knight shift than expected in the non-interacting limit. The electronic ground state contains skyrmions

state in the low-temperature limit.³⁸ These data also drop off more rapidly with increasing temperature than data taken in either the integral ($\nu = 1$) or the fractional ($\nu = 1/3$) quantum Hall regimes. Both observations are qualitatively consistent with the emerging picture that the $\nu = 1/2$ state is best described as a compressible (i.e., gapless) state of composite fermions.^{69–77} OPNMR measurements of $P(T, \nu = 1/2)$ and of the temperature dependence of the nuclear spin-lattice relaxation rate $R_1(T, \nu = 1/2)$ provide important constraints^{38,78} on the theoretical description of the $\nu = 1/2$ state and shed new light on the nature of the composite fermion.^{79,80}

Figure 5 Temperature dependence of the electron spin polarization of a GaAs quantum well at integral ($\nu = 1$) and fractional ($\nu = 1/2$, $\nu = 1/3$) filling factors, determined from Knight shifts in OPNMR spectra. Two-dimensional electron systems at $\nu = 1$ and $\nu = 1/3$ exhibit the integer and fractional quantum Hall effects, respectively. The electronic ground state at $\nu = 1/2$ is described theoretically as a compressible (i.e., gapless) state of composite fermions

Figure 6 Dependence of the ^{71}Ga Knight shift on filling factor (open circles), obtained from OPNMR measurements on a multiple quantum well sample with 30-nm thick GaAs wells and 180-nm thick $\text{Al}_{0.1}\text{Ga}_{0.9}\text{As}$ barriers at a field of 7.05 T and 1.55 K. The filling factor was varied by tilting the sample in the field. The solid line is the theoretical curve for noninteracting electrons in a two-dimensional system. The dashed lines are fits to the data, assuming a skyrmion model in which each skyrmion carries an effective spin of 1.8, or 3.6 times the spin of a single electron. Data of this type provided the first experimental evidence for skyrmions in two-dimensional electron systems. (Reprinted from Ref.³⁴)

OPNMR data on GaAs quantum wells, such as the data in Figure 6, also provided the initial experimental evidence^{34,35} for novel charged spin-texture excitations^{62,63} called skyrmions in 2DES. To understand the meaning of a skyrmion state, consider the ground state of the QHFM at $\nu = 1$ (Figure 4(a)), and then add one electron (at fixed temperature), to move

to $\nu = 1 + \epsilon$. By the Pauli exclusion principle, the spin of the additional electron must be reversed with respect to the electron spins at $\nu = 1$. However, theory predicts a more dramatic effect: to minimize electrostatic repulsions, nearby electron spins will twist as well, making nearest neighbors more nearly parallel, until the reduction in Coulomb energy is balanced by the higher Zeeman energy of multiple reversed electron spins.⁵⁹ The resulting many-body state, a skyrmion, has one more electron but many more net reversed spins (~ 3 per additional electron in most experiments), relative to the $\nu = 1$ ground state. As shown in Figure 6, $K_s(\nu)$ at low temperature, and thus $P(\nu)$, drops rapidly³⁴ as more skyrmions (or antiskyrmions, corresponding to $\nu = 1 - \epsilon$) are added to the system^{63,81} by moving farther above or below $\nu = 1$. A similar drop has been reported⁸² near $\nu = 3$. The presence of many skyrmions also leads to a strong dependence of R_1 on ν near the integral quantum Hall condition.³⁵ From a purely phenomenological standpoint, the effects of varying ν can be quite dramatic: at 2.1 K and 7.05 T, the spin-lattice relaxation rate of ^{71}Ga nuclei in a GaAs quantum well near $\nu = 1$ changes by a factor of 20 when the sample is rotated by only 3° ! Similar effects have subsequently been observed in specific heat measurements.^{83,84}

As Figure 4(c) shows, the size of the skyrmion is expected to be much less than that of spin waves [which are extended objects, Figure 4(b)], but also much greater than the inter-nuclear spacing of roughly $3 \text{ \AA}$. The spatial extent of the skyrmion is relatively unimportant at temperatures where skyrmions are delocalized and the OPNMR spectra are motionally narrowed³⁷ (i.e., the time-averaged value of $P(T, \nu)$ is invariant to translation in the plane of the quantum well).

Figure 7 Dependences of the Knight shift (filled symbols) and quantum well NMR linewidth (open circles) on temperature, from ^{71}Ga OPNMR measurements on GaAs quantum wells at filling factors $\nu = 1.00$ (triangles), 0.969 (diamonds), 1.045 (squares), and 0.949 (circles). Lines are guides to the eye. The non-monotonic temperature dependence of the linewidth indicates a transition from the motionally narrowed limit at higher temperatures towards the static limit at lower temperatures, where the motion in question is translation of skyrmions in the plane of the quantum well

However, for $\nu \neq 1$, Figure 7 shows that lowering the temperature causes the width of the quantum well lineshape (open symbols) first to increase and then to decrease,⁸⁵ in stark contrast with the temperature independence of the quantum well linewidth at $\nu = 1$. Similar trends were uncovered in earlier measurements³⁷ near $\nu = 1/3$. The non-monotonic temperature dependence of the linewidth in Figure 7 is consistent with the evolution of the quantum well OPNMR lineshape from the motionally narrowed regime to the static regime as the temperature is lowered. Specifically, the motion at higher temperatures is that of delocalized skyrmions. As the temperature is lowered, fluctuations in local hyperfine fields freeze out as the skyrmions become localized. With spectra approaching the frozen limit, future OPNMR measurements should provide new details about the spatial distribution of skyrmions in a 2DES and the nature of the many-skyrmion ground state, which may possess unusual order.^{86–92}

5 CONCLUDING REMARKS

More than three decades have passed since the first demonstration by Lampel⁶ of optical pumping of nuclear spins in a semiconductor and of directly detected, optically pumped NMR. As described in this chapter, Lampel's early work has been followed by a large number of interesting methodological extensions, including the development of ODNMR techniques, time-domain ODNMR, and high-field OPNMR, and important applications, most notably the use of OPNMR as a probe of the properties of conduction electrons in two-dimensional systems in the quantum Hall regime of low temperatures and high magnetic fields. Because of the practical importance of sensitivity enhancement in all areas of NMR and the commercial and scientific importance of semiconductor devices, investigations and applications of optical pumping effects in semiconductors are certain to continue. Likely areas for future research include clarifications of the physical mechanism of optical pumping in semiconductors, investigations of optical pumping effects in other semiconductor materials and other quantum-confined structures (e.g., quantum dots), further development of all-optical NMR methods, and possibly the use of optically pumped semiconductor wafers as sources of nuclear spin polarization for sensitivity enhancement in NMR measurements on organic or biological materials deposited on the semiconductor surface.²⁷

Biographical Sketches

Robert Tycko, b 1959. A.B., 1980, Princeton University. Ph.D., 1984, University of California at Berkeley. Began his career at AT&T Bell Laboratories, where he developed new solid state NMR methods, such as zero-field NMR in high field, and applied solid state NMR to problems in condensed matter physics. Moved to the National Institutes of Health in 1994, and now develops and applies solid state NMR methods for structural studies of biopolymers. Approx. 100 papers on all areas of magnetic resonance. Research interests: optical pumping, NMR theory and methodology, structure of proteins and amyloid fibrils.

Sean E. Barrett, b 1965. A.B., 1987, Princeton University. Ph.D., 1992, University of Illinois at Urbana-Champaign. Recipient of the 1995 William L. McMillan Award for outstanding contributions to condensed matter physics, in particular the development at AT&T Bell Laboratories of optically pumped NMR as a probe of two-dimensional electron systems. Approx. 25 papers on NMR in condensed matter physics. Research interests: optical pumping, two-dimensional electron systems, high-temperature superconductivity.

Parahydrogen Enhanced NMR Spectroscopic Methods: A Chemical Perspective

1 INTRODUCTION

The study of the mechanisms of catalytic action of coordination compounds has become an important part of modern chemistry. Many different spectroscopic methods have been applied with the coupling of time-resolved laser spectroscopy, for example, where matrix isolation provides an approach that has enabled the direct detection of unsaturated intermediates and the rationalization of their subsequent reactivity. The characterization of species in solution can, however, be more accurately achieved using NMR spectroscopy and since this technique also offers the opportunity to probe stereochemistry and monitor kinetic activity, it has many advantages over methods where only a limited number of parameters can be examined. Unfortunately, the inherent low sensitivity of NMR results in the fact that the most reliably studied reactions correspond to those where high concentrations of substrate are available. Since the study of reaction mechanisms requires the detection of reaction intermediates that are present in low concentration, NMR might initially be thought to be unsuitable for this work.

One route to achieving high concentrations of reactive species is to use photochemistry to prepare them at temperatures where they are stable. Using this approach Ball recently characterized the first sigma alkane complex by NMR spectroscopy.¹ A second approach that is becoming

more widely accepted involves the independent synthesis of molecules in specific spin-states. Under these conditions, the observable NMR signals have strengths that are not governed by Boltzmann statistics but rather by the efficiency of the initial spin state preparation. Parahydrogen with a lifetime of one year provides one example of where spin state synthesis has been used successfully in NMR. Bowers and Weitekamp first suggested and later proved that significantly enhanced NMR signals could be obtained from molecules that were formed by the addition of dihydrogen enriched in the *para* spin state.² This article is devoted to describing the chemical applications of *para*-hydrogen enhanced NMR spectroscopy that are illustrated in Scheme 1.

Scheme 1 Summary of chemical applications of *p*-H₂ enhanced NMR spectroscopy

2 GENERAL PRINCIPLES BEHIND THE PARAHYDROGEN EFFECT

The *para*-isomer of H₂ possesses the anti-symmetric spin configuration ($\alpha\beta - \beta\alpha$). Triply degenerate *ortho*-isomers with symmetric spin configurations ($\alpha\alpha$, $\beta\beta$, $\alpha\beta + \beta\alpha$) are also possible. For the synthesis of *para*-H₂ to be viable these two forms must have sufficiently long lifetimes to enable their separation. Fortunately, interconversion between *ortho*- and *para*-forms is symmetry forbidden with conversion times approaching one year under normal conditions. The difference in internal energy between the two forms of H₂ enables their separation: *para*-H₂ is restricted to even values of J, the rotational quantum number, and *ortho*-H₂ to odd values of J.

Para-hydrogen enrichment of hydrogen can be achieved by simply cooling H₂ to 77 K in a glass bulb that contains a small amount of iron oxide to catalyze the interconversion process.³ The resulting *para*-enriched H₂ (*p*-H₂) can be transferred to an NMR tube with a Young's valve prior to in situ NMR monitoring. An alternative approach that generates a continuous stream of *p*-H₂ via passage through a U-shaped metal tube containing activated charcoal that is cooled in a bath of liquid nitrogen to 77 K has also been reported.⁴ Hydrogen gas is then bled through a capillary into the NMR solution for a few seconds, the capillary removed and data acquisition started.⁵ Both these methods generate a mixture of 51% *para*-hydrogen and 49% *ortho*-hydrogen via equilibration at 77 K.

The initial article by Bower's discusses the NMR aspects of the *p*-H₂ approach.⁵ However, the resulting spectral effect can be easily understood by reference to Figure 1, which shows

Figure 1 Energy level diagram and ^1H spectral features for a metal dihydride with magnetically distinct protons H_a and H_b . Population differences indicate the situation that arises when the product is formed from $p\text{-H}_2$

the situation that exists for a metal complex that contains two inequivalent hydride ligands, H_a and H_b , that are spin–spin-coupled. Since the nuclear spins of H_a and H_b can be arranged in the orientations $\alpha\alpha$, $\alpha\beta$, $\beta\alpha$, $\beta\beta$ the associated ^1H NMR spectrum consists of two distinct doublet resonances for protons H_a and H_b . When protons H_a and H_b originate from a *para*-hydrogen molecule and the addition process is spin correlated, the starting ($\alpha\beta - \beta\alpha$) spin state converts into $\alpha\beta$ and $\beta\alpha$ product states. Consequently, the population differences, and hence signal intensities, for the resonances due to the metal hydride ligands show ‘emission’ and ‘absorption’ character and are enhanced over their normal levels. The results of this process have been referred to by the terms PASADENA (Parahydrogen And Synthesis Allow Dramatically Enhanced Nuclear Alignment) and PHIP (ParaHydrogen Induced Polarization) and are rigorously treated elsewhere.^{6,7}

3 THE ROLE OF H_2

H_2 plays an important role in many catalytic reactions, with the addition of H_2 to a metal center often involving the formation of an intermediate containing an $\eta^2\text{-H}_2$ interaction prior to the formation of the corresponding metal dihydride. From a synthetic perspective, one of the easiest routes to prepare a metal dihydride complex therefore involves the reaction of a suitable precursor with H_2 . Such reactions can be readily monitored by NMR spectroscopy since the associated hydride resonances are normally shifted to low frequency.

When metal hydride complexes play a role in a catalytic transformation such as hydrogenation, the most interesting complexes have short lifetimes and are therefore present in very low concentration. Halpern and Brown most elegantly illustrated the importance of the detection of minor species during their NMR studies of asymmetric hydrogenation. These studies involved the hydrogenation of prochiral enamides by cationic rhodium complexes containing a chiral diphosphine such as DIPAMP. Normal NMR methods revealed that the least stable enamide isomer reacted substantially faster with H_2 and was responsible for the observed enantiomeric selectivity in the corresponding hydrogenation product.⁸ When reactions with $p\text{-H}_2$ are studied the detection of minor components in reactions becomes much easier.

4 STRATEGIES FOR USING PARAHYDROGEN

When $p\text{-H}_2$ adds to a substrate to generate a product with two distinct, and coupled protons, the product operator $I_z^A I_z^X$

defines the initial magnetization. In this notation the subscripts refer to the orientation of the magnetization in a Cartesian coordinate system with z along B_0 , the applied magnetic field, and the superscripts refer to the nuclei A and X . Application of a radio frequency pulse of flip angle α to this starting state generates four new terms as shown in equation (1).

$$2I_z^A I_z^X \longrightarrow 2I_z^A I_z^X \cos^2 \alpha + 2I_X^A I_z^X \cos \alpha \sin \alpha + 2I_z^A I_X^X \cos \alpha \sin \alpha + 2I_X^A I_X^X \sin^2 \alpha \quad (1)$$

The first and last terms correspond to zero and double quantum coherence and are not directly observable. The two remaining terms are observable and correspond to magnetization that is oriented anti-phase with respect to the scalar coupling J_{AX} . The contribution of these terms is maximized with a $\pi/4$ pulse. However, the $I_z^A + I_z^X$ starting point for conventional magnetization generates maximum signal with a $\pi/2$ pulse as shown in equation (2).

$$I_z^A + I_z^X \longrightarrow I_z^A \cos \alpha + I_z^X \cos \alpha + I_X^X \sin \alpha + I_X^A \sin \alpha \quad (2)$$

Clearly, the situations with normal and $p\text{-H}_2$ based magnetization are different and consequently, great care must therefore be taken when multiple pulse experiments are used in conjunction with $p\text{-H}_2$ based magnetization. It should be noted however, that standard magnetization can be achieved via selective excitation methods or simple refocusing with respect to J_{HH} .

The ^1H spectrum shown in Figure 2 was collected using single a $\pi/4$ pulse on a benzene- d_6 solution of $\text{IrCl}(\text{CO})(\text{PPh}_3)_2$ at 323 K in the presence of 3 atm of $p\text{-H}_2$. The two signals at $\delta -6.65$ and -17.47 are due to the hydride ligands of $\text{IrH}_2\text{Cl}(\text{CO})(\text{PPh}_3)_2$ and are split into emission and absorption components (e/a) in accordance with the generation of the $I_z^A I_X^X$ and $I_X^A I_z^X$ spin states indicated above. This result can also be understood by reference to the non-Boltzmann spin state populations shown in Figure 1 that have opposite sense for transitions separated by J_{HH} .

5 DEMONSTRATION OF THE $p\text{-H}_2$ EFFECT

The first reported experimental observations attributed to the PASADENA/PHIP effect were those of Bowers

Figure 2 ^1H NMR spectrum (400 MHz, 295 K) showing the appearance of the hydride resonances of $\text{IrH}_2\text{Cl}(\text{CO})(\text{PPh}_3)_2$ (structure inset) when the product is generated from a 0.1 mM solution of $\text{IrCl}(\text{CO})(\text{PPh}_3)_2$ in benzene- d_6 under 3 atm of $p\text{-H}_2$

and Weitekamp.⁶ In this study, Wilkinson's catalyst was used to convert acrylonitrile (CH_2CHCN) to propionitrile ($\text{CH}_3\text{CH}_2\text{CN}$) under an atmosphere of $p\text{-H}_2$.⁹ NMR spectra revealed enhancements of between 100 and 200 fold in the ^1H resonances of propionitrile for positions corresponding to nuclei originally in $p\text{-H}_2$. The spectra also contained weak, and very broad, $p\text{-H}_2$ enhanced resonances for the hydride ligands of the dihydride complex $\text{RhH}_2\text{Cl}(\text{PPh}_3)_3$.

Since this first report the resonances of both inorganic complexes and organic substrates have been successfully probed using $p\text{-H}_2$. This article now focuses on helping the reader understand how $p\text{-H}_2$ can help them study chemical systems. A number of other articles review more clearly the chronological development of this effect.¹⁰

6 APPLICATIONS TO INORGANIC SYSTEMS

Since the process of oxidative addition of hydrogen proceeds to increase the electron count of a metal center by two units, 16 electron square planar d^8 complexes often feature as systems that readily add H_2 . The often cited reaction of the d^8 complex $\text{IrCl}(\text{CO})(\text{PPh}_3)_2$ with H_2 follows a concerted pathway, with addition over the OC-Ir-Cl axis selectively placing the hydrides in a mutually *cis* orientation. When this reaction was studied with $p\text{-H}_2$, at 295 K where the addition is irreversible, the corresponding ^1H NMR spectrum contained polarized hydride resonances for *cis-trans*- $\text{IrH}_2(\text{CO})(\text{PPh}_3)_2\text{Cl}$ and the new product *cis-cis*- $\text{IrH}_2(\text{CO})(\text{PPh}_3)_2\text{Cl}$. The enhanced hydride resonance associated with this minor species were only visible with $p\text{-H}_2$ and indicated that H_2 addition over the P-Ir-P axis of

$\text{IrCl}(\text{CO})(\text{PPh}_3)_2$ is possible. The successful observation of this new species using the $p\text{-H}_2$ approach provides just one illustration of the many that show it is possible to see previously unobserved complexes via this route.

The exchange of $p\text{-H}_2$ into $\text{Ir}(\text{H})_2\text{Cl}(\text{CO})(\text{PPh}_3)_2$, and the complexes $\text{Rh}(\text{H})_2(\text{PMe}_3)_4\text{Cl}$, and $\text{Rh}(\text{H})_2(\text{PMe}_3)_3\text{Cl}$ has been used to show that the monitoring of $p\text{-H}_2$ enhanced products can be achieved by 2D COSY, HMQC and NOESY methods. The observation of heteronuclei, including low sensitivity nuclei such as ^{103}Rh , the determination of heteronuclear coupling constants and the measurement of their relative signs was demonstrated (Figure 3). The dihydride addition product $\text{Ir}(\text{H})_2\text{Cl}(\text{CO})(\text{PPh}_3)_2$ was shown to contain a *trans* labilized carbonyl ligand, and substitution with appropriate phosphines demonstrated to bring about the formation of metal phosphine complexes with new ligand spheres. An appropriately modified NOESY experiment enabled the rapid probing of the structural arrangements of these products and the monitoring of dihydride exchange. In the case of $\text{Ir}(\text{H})_2\text{Cl}(\text{PPh}_3)_3$, dihydride exchange proceeded mainly via the intermediate $\text{Ir}(\text{H})_2\text{Cl}(\text{PPh}_3)_2$, which was shown to contain inequivalent hydrides.

Reactions of the d^8 -rhodium complexes $\text{RhX}(\text{CO})(\text{PR}_3)_2$ where $\text{X} = \text{Cl}, \text{Br}, \text{I}$ and $\text{R} = \text{Ph}, \text{Me}$ with $p\text{-H}_2$ have also been described.¹¹ However, unlike $\text{IrCl}(\text{CO})(\text{PPh}_3)_2$, these complexes had not previously been seen to react with dihydrogen. The $\text{RhX}(\text{CO})(\text{PPh}_3)_2$ complexes were shown to yield unexpected dinuclear products of the general formula $\text{H}_2\text{Rh}(\text{PPh}_3)_2(\mu\text{-X})_2\text{Rh}(\text{PPh}_3)(\text{CO})$, where the hydrides that are *trans* to the halide bridges are rendered inequivalent by the ligands on the Rh(I) center. Since the initial dihydrogen activation product $\text{RhH}_2\text{X}(\text{CO})(\text{PPh}_3)_2$ was not detected it was suggested that facile CO loss led to the generation of

Figure 3 Selected cross peaks (positive contours) and projections from ^1H - ^{31}P and ^1H - ^{103}Rh correlation spectra of $\text{Rh}(\text{H})_2(\text{PMe}_3)_3\text{Cl}$ obtained with $p\text{-H}_2$ in CD_2Cl_2 at 313 K. (a) ^{31}P decoupled 500 MHz ^1H - ^{31}P correlation spectrum showing cross peaks between H and P indicated in inset structure. (b) ^{103}Rh decoupled 500 MHz ^1H - ^{103}Rh correlation spectrum showing correlated transitions between H and Rh

Scheme 2 Suggested route to $\text{H}_2\text{Rh}(\text{PPh}_3)_2(\mu\text{-Cl})_2\text{Rh}(\text{PPh}_3)(\text{CO})$ as detected in the reaction of $\text{RhCl}(\text{CO})(\text{PPh}_3)_2$ with $p\text{-H}_2$

the unsaturated species $\text{RhH}_2\text{X}(\text{PPh}_3)_2$. The formation of these reaction products was suggested to involve the co-ordinatively unsaturated species $\text{RhH}_2\text{X}(\text{PPh}_3)_2$ as shown in Scheme 2.

When the reaction of $\text{RhCl}(\text{CO})(\text{PMe}_3)_2$ was monitored at 342 K under 3 atm of $p\text{-H}_2$, the major product corresponded to $\text{H}(\text{Cl})\text{Rh}(\text{PMe}_3)_2(\mu\text{-H})(\mu\text{-Cl})\text{Rh}(\text{PMe}_3)(\text{CO})$ with bridging and terminal hydrides. However, when $\text{RhI}(\text{CO})(\text{PMe}_3)_2$ was monitored, NMR spectroscopy enabled the detection of five new species. At 348 K the most intense signals were shown to originate from the analogous complex $(\text{H})(\text{I})\text{Rh}(\text{PMe}_3)_2(\mu\text{-H})(\mu\text{-I})\text{Rh}(\text{CO})(\text{PMe}_3)$ in which the hydrido-bridge is *trans* to phosphine. A minor reaction product corresponding to the isomer of $(\text{H})(\text{I})\text{Rh}(\text{PMe}_3)_2(\mu\text{-H})(\mu\text{-I})\text{Rh}(\text{CO})(\text{PMe}_3)$ with the hydrido-bridge *trans* to carbonyl was also characterized at this temperature. The remaining products were reported to have the structures $(\text{H})_2\text{Rh}(\text{PMe}_3)_2(\mu\text{-I})_2\text{Rh}(\text{CO})(\text{PMe}_3)$, $\text{Rh}(\text{H})_2\text{I}(\text{PMe}_3)_3$ and $\text{HRh}(\text{PMe}_3)_2(\mu\text{-H})(\mu\text{-I})_2\text{Rh}(\text{PMe}_3)(\text{CO})$. These reactions were shown to be consistent with results from density functional theory that predicted all four structural types correspond to reaction intermediates rather than transition states. A typical ^1H NMR spectrum produced from such a reaction is shown in Figure 4.

Significantly, when the reactions involving $\text{RhCl}(\text{CO})(\text{PMe}_3)_2$ with $p\text{-H}_2$ were monitored in the presence of

styrene, a dramatic increase in hydride signal enhancements was observed. This facilitated the detection of the $(\text{H})_2\text{Rh}(\text{PMe}_3)_2(\mu\text{-Cl})_2\text{Rh}(\text{CO})(\text{PMe}_3)$ in addition to $\text{HRh}(\text{PMe}_3)_2(\mu\text{-H})(\mu\text{-Cl})_2\text{Rh}(\text{CO})(\text{PMe}_3)$.¹¹ This result demonstrated that a sacrificial alkene can dramatically extend the sensitivity of the parahydrogen methods by promoting H_2 cycling.

The reactions of stable 18 electron complexes such as $\text{RuH}_2(\text{CO})_2(\text{PMe}_3)_2$ have also been monitored with $p\text{-H}_2$. When a C_6D_6 solution containing <1 mg of $\text{RuH}_2(\text{CO})_2(\text{PMe}_3)_2$ was monitored under normal- H_2 , only the *tcc* isomer was observed after 10 000 scans. The detection and conclusive identification of the elusive *ccc* isomer became possible with the onset of rapid free $p\text{-H}_2\text{-RuH}_2$ exchange at 328 K.¹² In addition, it was reported that the introduction of a ^{13}CO label made the major *tcc* isomer $p\text{-H}_2$ active by virtue of the second order spin system that is created. At the time, this represented the first report of $p\text{-H}_2$ activity in a system containing a square planar $\text{MH}_2(\text{CO})(^{13}\text{CO})$ core and served to illustrate that the need for magnetically distinct hydrides could be satisfied synthetically. The reactions of a number of other dihydride complexes including $\text{Ir}(\text{CO})(\text{PPh}_3)(\text{Et}_2\text{dtc})$, $\text{Pt}(\text{H})_2((\text{dpp})_2\text{mop})$ [where $((\text{dpp})_2\text{mop}) = \text{Ph}_2\text{PCH}_2\text{CH}(\text{Me})\text{OPPh}_2$] have also been explored using this approach (Figure 5).

Figure 4 400 MHz $^1\text{H}\{^{31}\text{P}\}$ NMR spectrum showing the hydride region after warming a sample of $\text{RhI}(\text{CO})(\text{PMe}_3)_2$ with $p\text{-H}_2$ in C_6D_6 to 348 K. Selected product resonances indicated via H_a , H_b and H with assignments according to the inset pictures

Figure 5 500 MHz ^1H - ^{31}P correlation spectrum of $\text{PtH}_2(\text{Ph}_2\text{PCH}_2\text{CH}(\text{Me})\text{OPPh}_2)$ at 298 K in toluene- d_8 under $p\text{-H}_2$

Figure 6 400 MHz ^1H NMR spectra for the inset complex obtained with $p\text{-H}_2$. The larger H-H splitting in the right trace is due to the hydride ligand that is *trans* to CO. It is twice the size of corresponding splitting for the left trace

It has also been shown that trihydrides such as $\text{IrH}_3(\text{CO})_x(\text{PR}_3)_y$ [$x = 2$ and $y = 1$; $x = 1$ and $y = 2$; $\text{PR}_3 = \text{PPh}_3$, PMe_3 and AsMe_2Ph] can be examined with $p\text{-H}_2$. These studies have provided a number of interesting observations. Firstly, the ^1H NMR spectra of the isomers of $\text{IrH}_3(\text{CO})(\text{PPh}_3)_2$, with *trans* phosphines and *mer*-hydrides and with *cis* phosphines and *fac*-hydrides, yield enhanced hydride resonances. The two polarized hydride resonances of the *mer*-isomer were expected to appear as doublets and triplets respectively in the ^{31}P decoupled spectrum with peak separations J_{HH} . However, with $p\text{-H}_2$, while the observed signals have relative intensities of 2:1 their anti-phase line separation is 4.4 and 8.8 Hz respectively. This indicates that the central feature of the triplet is no longer visible as shown in Figure 6.¹³

This observation has been explained by reference to the populations of the eight associated spin wave-functions of the trihydride (AX_2). While four wave-functions are simple products of the form $\alpha\alpha\alpha$, $\alpha\beta\beta$, $\beta\alpha\alpha$ and $\beta\beta\beta$, four belong to combinations of the form $\alpha(\alpha\beta - \beta\alpha)$, $\alpha(\alpha\beta + \beta\alpha)$, $\beta(\alpha\beta - \beta\alpha)$ and $\beta(\alpha\beta + \beta\alpha)$. Exchange with $p\text{-H}_2$ ($\alpha\beta - \beta\alpha$ spin state) involves the A and one X nucleus, with the result that the underlined states become equally populated while the $\alpha\alpha\alpha$ and $\beta\beta\beta$ states are unpopulated. Consequently, visible transitions for nucleus A, correspond to spin flips $\alpha\alpha\alpha \leftrightarrow \beta\alpha\alpha$ and $\alpha\beta\beta \leftrightarrow \beta\beta\beta$, and the outer lines of the triplet, separated by $2J_{\text{AX}}$, and are seen in emission and absorption. The central line, corresponding to the transitions $\alpha(\alpha\beta - \beta\alpha) \leftrightarrow \beta(\alpha\beta - \beta\alpha)$ and $\alpha(\alpha\beta + \beta\alpha) \leftrightarrow \beta(\alpha\beta + \beta\alpha)$, vanishes because the associated levels have

identical populations. Examination of the four symmetry allowed transitions for X_2 reveals that observable spin flips connect $\alpha\alpha\alpha \leftrightarrow \alpha(\alpha\beta + \beta\alpha)$ and $\beta(\alpha\beta + \beta\alpha) \leftrightarrow \beta\beta\beta$. These transitions, separated by $J_{\text{AX}}(J_{\text{HH}})$, are also visible as emission and absorption signals, with twice the overall intensity seen for the signal due to H_A , the hydride that is *trans* to CO.

Eisenberg et al. have reported studies on the reaction of the benzyne-hydride complex ($\text{Cp}_2^*\text{Ta}(\text{C}_6\text{H}_4)\text{H}$) with $p\text{-H}_2$.¹⁴ At 273 K, the complex reacts to form a new phenyl dihydride complex, $\text{Cp}_2^*\text{Ta}(\text{C}_6\text{H}_5)_2\text{H}_2$, which yields enhanced hydride resonances with $p\text{-H}_2$. This complex proceeds to eliminate benzene and react with H_2 to form the trihydride complex $\text{Cp}_2^*\text{TaH}_3$. The central hydride component of the proton resonance due to the central hydride ligand is again absent under PHIP conditions.

A number of recent studies have involved the examination of clusters with $p\text{-H}_2$. Up to this point this article has referred to a number of straightforward examples in which the nuclei originating in parahydrogen are transported into magnetically distinct environments. One potential drawback of the parahydrogen technique is therefore the need to create a product with magnetically inequivalent hydrides. Surprisingly, a number of instances have been described in the literature where enhanced signals are observed for pairs of magnetically equivalent protons.^{12,15} Aime and Canet elegantly illustrated the origin of this effect by reference to the addition of parahydrogen to $\text{Os}_3(\text{CO})_{10}(\text{NCCH}_3)_2$.¹⁶ This reaction first yields two isomers of $\text{H}(\mu\text{-H})\text{Os}_3(\text{CO})_{10}(\text{NCCH}_3)$ which react further to form $\text{H}_2\text{Os}_3(\text{CO})_{10}$, a species in which

the two hydrogen nuclei are magnetically equivalent. They demonstrated that the observation of an enhanced hydride signal for $\text{H}_2\text{Os}_3(\text{CO})_{10}$ necessitates the involvement of an intermediate with inequivalent hydrides, and subsequent cross-correlation between dipolar interactions and chemical shift anisotropy. These workers have also examined the reaction of $\text{Ru}_3(\text{CO})_{11}(\text{NCCH}_3)$ with parahydrogen.¹⁷ The observation of an enhanced emission signal for molecular hydrogen was interpreted to indicate the reversible interaction of $p\text{-H}_2$ via the formation of a Ru_3 cluster with inequivalent hydrides. The reactions of the cluster series $\text{Ru}_3(\text{CO})_9(\text{PR}_3)_3$, $\text{Ru}_3(\text{CO})_{10}(\text{PR}_3)_2$ and $\text{Ru}_3(\text{CO})_{11}(\text{PR}_3)$ [$\text{PR}_3 = \text{PPh}_3$, PMe_2Ph and PCy_3] with $p\text{-H}_2$ have also been examined.¹⁸ These studies revealed that related products such as $\text{H}(\mu\text{-H})\text{Ru}_3(\text{CO})_8(\text{PPh}_3)_3$ are formed, and that in the case of $\text{PR}_3 = \text{PPh}_3$, cluster fragmentation leads to the observation of signals for the meridional isomer of $\text{Ru}(\text{CO})_3(\text{H})_2(\text{PPh}_3)$.

Another system in which PHIP has enabled the detection of dihydride species involves rhodium complexes with tin trichloride ligands. Rhodium monohydrides such as $[\text{HRh}(\text{SnCl}_3)_5]^{3-}$ yielded dihydride complexes upon reaction with phosphines and hydrogen, the species were again detectable only because of the PHIP effect.¹⁹ Dihydride complexes of the form $\text{Rh}(\text{H})_2(\text{SnCl}_3)(\text{PR}_3)_3$ were later shown to be obtainable via the reaction of $[\text{RhCl}(\text{CO})_2]_2$ with SnCl_2 and three equivalents of PR_3 and $p\text{-H}_2$.²⁰

When Brown and Bargon revisited asymmetric hydrogenation with $p\text{-H}_2$, the detection and characterization of a rather unusual hydride complex was achieved using PHIP.²¹ At -40°C in methanol with an enamide substrate, two polarized hydride resonances were observed at $\delta -1.9$ and $\delta -18.9$ at the same time as PHIP effects were detected in the signals of the hydrogenation product. The use of other substrates produced analogous hydride resonances at slightly different chemical shifts, whilst the simultaneous use of two different enamides produced two distinct species. Furthermore, when the enamide was ^{13}C labeled at the $\beta\text{-C}$ position, an extra splitting of 86 Hz was observed in the higher frequency hydride resonance, whereas a ^{13}C label in the $\alpha\text{-C}$ position produced only a small additional splitting of 3 Hz. This experimental evidence was interpreted to indicate the detection of a species in which one hydride had been transferred to the substrate and existed as an agostic hydrogen atom, bound between the rhodium nucleus and the $\beta\text{-carbon}$. The lower frequency resonance corresponded to a signal from a hydride *trans* to the carbonyl oxygen of the chelating ligand. Support for this structure was obtained from DFT calculations, which located an agostic species as a significant energy minimum, presumably as a direct precursor of an alkyl hydride.

7 APPLICATIONS TO ORGANIC SYSTEMS

A particularly important class of reactions studied by $p\text{-H}_2$ corresponds to metal catalyzed hydrogenation. Since the $\text{RhCl}(\text{PPh}_3)_3$ mediated hydrogenation of acrylonitrile was described using this approach, a large body of literature has developed. One of the earliest reports showed that enhanced resonances for styrene observed during the $\text{Rh}_2(\text{CO})_2(\text{dppm})_2$ catalyzed hydrogenation of phenylacetylene, resulted from $p\text{-H}_2$ rather than Chemically Induced Dynamic Nuclear Polarization (CIDNP), as had been originally

Figure 7 40 MHz ^1H NMR spectrum illustrating the effect of polarization on the signals for the resonances in ethylbenzene

suggested.^{22,23} Similar polarization effects were reported when $[\text{Rh}_3\text{Cl}_2\text{H}_2(\text{CO})_2(\text{Ph}_2\text{PCH}_2)_2\text{-PPh}_2]^+$ catalyzed the hydrogenation of phenylacetylene. The intensely polarized resonances at $\delta 6.57$ and $\delta 5.06$ confirmed *cis*, pairwise transfer of H_2 . Weaker polarization, via cross relaxation, was obtained for the geminal proton that did not originate from a H_2 molecule. Figure 7 illustrates a typical spectrum showing polarization in an organic product, in this case ethylbenzene.

Eisenberg then linked the occurrence of PHIP in the ^1H resonances of hydrogenation products to the mechanism of H_2 delivery to the substrate. For instance, the reaction of $d^8\text{-styrene}$ with $p\text{-H}_2$ in the presence of $\text{RuH}_4(\text{PPh}_3)_3$ produced PHIP effects for protons in the alkyl chain of the product ethylbenzene.²⁴ This requires that protons from a single H_2 molecule transfer to the styrene. When styrene was hydrogenated with $p\text{-H}_2$ by $\text{RuHCl}(\text{PPh}_3)_3$, weaker PHIP signals were observed in the ^1H resonances of ethylbenzene. Hydrogenation can therefore proceed via pairwise transfer of H_2 to the alkene. By demonstrating that $\text{RuHCl}(\text{PPh}_3)_2$ could not itself be the active catalytic intermediate, the authors were able to propose that the formation of $\text{RuH}_2(\text{PPh}_3)_2$ was possible. Thus $p\text{-H}_2$ enhanced NMR demonstrated that one of the pathways of $\text{RuHCl}(\text{PPh}_3)_3$ catalyzed hydrogenation involves a small but active quantity of $\text{RuH}_2(\text{PPh}_3)_2$.

Eisenberg and others have also shown that information about the reversibility of H_2 addition to a catalyst precursor can be deduced from PHIP spectra of a hydrogenation product. Reaction of $\text{PhC}\equiv\text{CH}$ with para-enriched hydrogen in the presence of $\text{RhCl}(\text{PPh}_3)_3$ for instance, results in weakly polarized resonances of the product styrene with the degree of polarization decaying rapidly.²⁵ When $\text{Rh}(\text{COD})(\text{dppe})^+$ was used, considerably larger enhancements were obtained which were observable for substantially longer. The extended period over which PHIP could be observed was taken to indicate that slow *ortho-para* equilibration was occurring. The authors concluded that while H_2 addition to the $\text{RhCl}(\text{PPh}_3)_3$ is reversible, irreversible addition occurs with $\text{Rh}(\text{COD})(\text{dppe})^+$.

Figure 8 Mechanism of hydrogen exchange accounting for the enhancement of signals in the substrate. Competing hydrogenation pathway not shown

Using a very different catalyst system, Bargon found evidence for the reversible hydrogen transfer into the alkene substrate.²⁶ With methylacrylate as the substrate, polarized ^1H resonances were observed for both the geminal protons in the starting material indicating the pairwise exchange of parahydrogen into these positions. The mechanism proposed to account for substrate hydrogenation as well as both mono and pairwise exchange of the geminal protons is shown in Figure 8.

Similar geminal proton exchange with $p\text{-H}_2$ was also observed during the hydrogenation of styrene by $[\text{Rh}(\text{COD})(\text{dppb})]\text{BF}_4$.²⁷ Interestingly, the co-ordination of the styrene to the metal center through the π -system of the phenyl ring of the substrate was proposed to assist the pairwise exchange process. This was demonstrated via the observation of a second set of enhanced signals, with identical multiplicity and J_{HH} coupling constants to those of ethylbenzene but with different chemical

Figure 9 Intramolecular nOe connections visible during catalysis of styrene hydrogenation with $[\text{Rh}(\text{dppb})]^+$

shifts.²⁸ This second pair of resonances was attributed to recently formed ethylbenzene molecules that remained co-ordinated to the catalyst complex. The co-ordination of product ethylbenzene to the catalyst fragment $[\text{Rh}(\text{dppb})]^+$ was later proven via a 1D NOESY experiment.²⁹ Selective irradiation of either of the two new protons of the bound ethylbenzene resulted in the observation of nOe connections to the ortho phenyl protons of the dppb ligand as shown in Figure 9. No nOe interactions with the catalyst were observed by irradiating either of the protons in free ethylbenzene. Equivalent results were obtained using a PHIP modified ROESY experiment.²⁹ The role of $p\text{-H}_2$ as a tool for probing hydrogenation products is therefore well established.

8 KINETIC MEASUREMENTS

The studies of catalytic systems have also resulted in the development of methods to investigate hydrogenation rates using $p\text{-H}_2$. With $\text{RuH}_4(\text{PPh}_3)_3$ as the catalyst for example, the nature of the polarization in the product molecules was found to be different for alkene and alkyne substrates.²⁴ While hydrogenation of d^8 -styrene yielded ethylbenzene resonances with multiplet polarization while alkynes, including $\text{PhC}\equiv\text{CH}$ and $\text{CH}_2=\text{CHO}_2\text{Me}$, resulted in the observation of the corresponding product alkenes with net polarization. Since multiplet polarization corresponds to hydrogenation inside the high magnetic field of the probe, while net polarization requires the reaction to proceed at weaker magnetic fields, it could be concluded that alkynes were being hydrogenated faster than the alkenes.

Rather more quantitative studies have also been performed. Eisenberg has analyzed the decay of polarization during a reaction to estimate the rate of hydrogenation and developed a methodology termed ROCHESTER (Rates Of Catalytic Hydrogenation Estimated Spectroscopically Through Enhanced Resonances).³⁰ This was achieved via the reduction of ethyl (Z)- α -acetamidocinnamate using the chiral catalyst $[\text{Rh}(\text{NBD})(\text{chiraphos})]\text{BF}_4$. Integration of the polarized resonances and those of the acyl methyl protons revealed that the rate of polarization decay matched the rate of hydrogenation. Furthermore, increasing the overall catalyst concentration resulted in a faster rate of both hydrogenation and polarization decay. Upon analysis, the estimated rate of hydrogenation was found to be comparable to that determined by Halpern using a different method.³¹ It should be noted that the catalyst was carefully chosen so that reversible addition of H_2 would not occur and lead to *ortho-para* equilibration.

Bargon and others have provided a detailed analysis of a modified ROCHESTER experiment.³² In this study, an automated procedure for saturating a solution with $p\text{-H}_2$ inside the NMR probe was presented. This had the advantage that no H_2 atmosphere remained above the solution once hydrogenation was complete and thus no diffusion between the solution and the gas phase occurred. A refined experimental method, termed DYPAS (DYnamic PASadena spectroscopy), was also outlined which allowed the determination of rates of intermediate formation and decay, as well as relaxation rates and the overall rate of hydrogenation. The pulse sequence used in this approach is illustrated in Figure 10. In principle, all processes leading to the formation and decay of a PHIP signal can be measured using this approach. The DYPAS

Figure 10 Pulse sequence for DYPAS experiment

method involves a variable delay between the addition of para-enriched hydrogen and a 45° read pulse, yielding a plot of signal intensity versus time (i.e., length of variable delay). Providing that a mechanistic scheme for the hydrogenation reaction exists, the decay of intensity can be described by a series of differential equations that can be solved to yield rate constants.

The potential of this method was illustrated using the $[\text{Rh}(\text{COD})(\text{dppb})]\text{BF}_4$ catalyst system, which, as described previously, yields product-catalyst complexes during the hydrogenation of styrene. Using a range of para-substituted styrenes, the rate constants for hydrogenation and product detachment from the catalyst were determined. The results revealed that increasing the electron donating ability of the para substituent both increased the overall rate of hydrogenation and decreased the rate of product detachment, presumably via increasing the binding potential of the arene ring to the rhodium center. The effects were sufficient for detachment to become rate limiting in the case of NH_2 substituted styrene. The more complex case of using a chiral catalyst and thus forming two diastereoisomeric product-catalyst complexes was also investigated in this way and a mechanistic scheme shown to be appropriate to the observed kinetic behavior.²³

9 NATURE OF POLARIZATION AND DIFFERENT SPIN SYSTEMS

Bargon has also investigated hydrogenation reactions that produce more complex spin systems than those described so far. The reaction of the complex $[\text{Rh}(\text{NBD})(\text{PPh}_3)_2]\text{PF}_6$ ($\text{NBD} = 2,5\text{-norbornadiene}$), with $p\text{-H}_2$ for example, initially produced polarized resonances attributable to 2-norbornene and at longer reaction times, norbornane resonances also displayed PHIP.³³ In the case of both products, while the added protons are chemically equivalent their magnet inequivalence activates the PHIP effect.

The presence of magnetic ^{13}C nuclei at natural abundance in hydrogenation products that are otherwise symmetrical is also sufficient to produce polarization in the ^1H spectra of product molecules. The hydrogenation of acetylene to ethene using para-enriched hydrogen for instance, yielded strongly polarized ^1H resonances corresponding to substrate molecules containing one ^{13}C nucleus, i.e., $\text{H}_2\text{ }^{12}\text{C}=\text{ }^{13}\text{CH}_2$.³⁴ Similar results were obtained in similar reactions with symmetrically substituted acetylenes and alkenes. Following the hydrogenation of $\text{CH}_3\text{O}_2\text{CC}\equiv\text{CCO}_2\text{CH}_3$, polarization was observed in the ^1H resonances of product alkene molecules that contained a ^{13}C nucleus at either the vinyl or carbonyl positions. In both

cases, spin-spin coupling interactions existed between these carbon nuclei and the added protons, with the final PHIP spectrum representing resonances from two distinct hydrogenation products. Enhancements were quoted as being of the order of 10^3 fold.

Using the same substrates, Bargon demonstrated that the NMR spectra of heteronuclei can be enhanced.³⁵ Enhancements of over 2580 fold in the ^{13}C spectrum of $\text{CH}_3\text{O}_2\text{CHC}=\text{CHCO}_2\text{CH}_3$ were recorded by simply acquiring a normal ^{13}C spectrum using a single 90° pulse. The enhancement in the NMR signals of the heteronuclei was shown to be greater when the protons from parahydrogen were transferred to chemically equivalent but magnetically distinct positions. Other methods of characterizing hydrogenation products have been developed. Bargon has used a number of modified INEPT experiments to obtain ^{13}C spectra of 1,4-diphenylbut-1-en-3-yne formed via the hydrogenation of 1,4-diphenylbutadiyne, including signal enhancements of over 300 fold.³⁶ Optimization of the experimental parameters allowed the transfer of polarization to a large part of the carbon skeleton of the product. In addition, a PHIP modified INADEQUATE experiment has been performed, allowing the measurement of J_{CC} coupling constants in the product molecule.³⁷ Similar experiments with a silane compound allowed acquisition of ^{29}Si resonances.

Bargon has also published a number of studies in which analysis of the polarization patterns in the hydrogenation products reveals details of the catalytic mechanism and reaction intermediates. The $\text{RhCl}(\text{PPh}_3)_3$ catalyzed hydrogenation of two different precursors to tetrahydrofuran for instance, produced different polarization patterns in the product.³³ This indicated that the ^1H PHIP spectra of hydrogenation products contain information about the origin of the product as well as the structure of the product itself.

The nature of the polarization in the organic hydrogenation product is also influenced by the nature of the catalyst used.³⁸ Information about the coordination geometry and lifetime of the intermediates can be deduced from the associated spectra. In the case of $\text{RhCl}(\text{PPh}_3)_3$, the dwell time of the hydrides in the dihydride alkene intermediate was estimated as at least 1.7 ms via this approach. In contrast, the polarization pattern obtained from the $[\text{Rh}(\text{COD})(\text{Ph-}\beta\text{-glup-OH})]\text{BF}_4$ system required that the catalytic intermediates contained hydrides in chemically equivalent positions, or, that once activated by the metal hydrogen transfer to the substrate was fast and irreversible. This latter proposal was consistent with other work performed on charged rhodium catalysts where the hydrogenation proceeds via alkene co-ordination followed by H_2 activation and rapid and irreversible hydrogen transfer. The spectral characteristics of the reaction products therefore provide

indirect information about the catalytic intermediates and the reaction mechanism.

10 PHIP AS A PROBE OF REGIO AND STEREOSELECTIVITY

PHIP spectra have also been used to investigate selectivity in hydrogenation reactions. It has for example, been shown possible to determine the position of hydrogen addition to the allene 1-methoxy-propa-1,2-diene, a process which can result in three different products after the reduction of one double bond.³⁹ The regioselectivities of three rhodium catalysts, [Rh(NBD)(PPh₃)₂]PF₆, RhCl(PPh₃)₃ and [Rh(COD)(Ph-β-glup-OH)]BF₄ towards this substrate were investigated via simulations of the PHIP spectra of each product. Analysis revealed considerable differences in the selectivity of the three catalysts under comparable reaction conditions. Whilst [Rh(COD)(Ph-β-glup-OH)]BF₄ does not favor the hydrogenation of either double bond, [Rh(NBD)(PPh₃)₂]PF₆ displays considerable selectivity for addition to the C=C bond closest to the methoxy substituent. In contrast RhCl(PPh₃)₃ fails to hydrogenate either bond.

1 INTRODUCTION

Recently, it has become clear that very large samples of highly polarized noble gas nuclei can be prepared by spin exchange with optically pumped alkali metal vapors. Several liter-atmospheres of gas, with nuclear polarizations of 10–90%, have already been obtained and put to good use in applications as diverse as targets for nuclear physics experiments,¹ the determination of how quarks produce the spins of protons and neutrons from high energy electron scattering on polarized ^3He targets,² the demonstration that Raman scattering of phonons through the nuclear spin–rotation interaction is responsible for the exceptionally slow relaxation of ^{129}Xe in frozen xenon,³ setting limits on the electric dipole moments of nuclei,⁴ studies of the pore structure of zeolites with highly polarized ^{129}Xe probe gas,⁵ and enhanced magnetic resonance imaging of lungs with highly polarized ^{129}Xe gas.⁶

This high nuclear polarization has its origins in photons of visible light. In 1948, Albert Kastler⁷ showed that it is possible to transfer much of the spin polarization of circularly polarized photons to the electron and nuclear spins of atoms. Kastler called this process *optical pumping*. Optical pumping has turned out to be practical for only a few atoms of the Periodic Table. The atomic vapors of alkali metals can be readily pumped⁸ with the strong, near-infrared and visible resonance lines of lamps—and in more recent years with tunable lasers. For optically pumped alkali metal vapors, both the unpaired electron spin and the nuclear spin are polarized. Mercury and cadmium atoms can also be polarized by optical pumping with the near-ultraviolet resonance lines.⁹ In the case of these diamagnetic atoms, all of the polarization is carried by the nucleus. Finally, the 2^3S state of metastable helium can be strongly polarized by optical pumping¹⁰ with the near-infrared $1.08\text{ }\mu\text{m}$ resonance line of the triplet spectrum.¹⁰ If ^3He is pumped by these methods, much of the angular momentum initially imparted by the photons to the electrons of metastable

helium atoms can be efficiently transferred to the nuclei of ground state ^3He atoms by metastability exchange collisions.¹¹

There are a few additional systems that have been polarized by optical pumping, but the great majority of work involves the alkali metal vapors, mercury vapor, or metastable helium atoms.¹² These systems have several features in common. All of the atomic species have very symmetric ground states, with spherically symmetric electron charge distributions, 2S states for the alkali metal atoms, a 1S state for mercury atoms, and a 3S state for metastable helium atoms. Such electronic states are exceptionally resistant to electron or nuclear spin depolarization during collisions. Furthermore, all of these systems can be pumped with near-visible light. Some important species, like hydrogen atoms, are very similar to alkali metal atoms and can be optically pumped, but the need for vacuum ultraviolet resonance radiation (Lyman α) has made direct optical pumping impractical. The widely used systems mentioned above all have adequate atomic number densities at convenient temperatures. Containing the gases and vapors presents manageable materials problems.

The extension of optical pumping methods to include spin exchange polarization of noble gas nuclei began with the demonstration by Carver and Bouchiat¹³ at Princeton University in 1960 that a substantial fraction of the electron spin angular momentum of optically pumped alkali atoms could be transferred to the nucleus of ^3He by spin exchange collisions. In 1978, Grover¹⁴ and a group at Litton Industries reported the extension of the spin exchange method from ^3He to isotopes of xenon and krypton. Extensive studies of the physics of spin exchange between the electrons of alkali metal atoms and noble gas nuclei were subsequently carried out at Princeton University.¹⁵

Although Kastler began his work with a few hundred microwatts of useful resonance light from lamps, it is now straightforward to get some watts of useful laser light for optical pumping experiments. A watt of $7947\text{ }\text{\AA}$ Rb resonance radiation is 4×10^{18} photons per second. Since one electron spin can be polarized for every photon absorbed by the Rb atoms, 4×10^{18} fully polarized electron spins can be produced per second. In favorable cases, about 10% of the electron spin polarization can be transferred by spin exchange to nuclear spin polarization of noble gases in the same container with the alkali-metal vapor. The spin can be accumulated for a time period on the order of T_1 , the longitudinal spin relaxation time of the noble gases. T_1 can be hours or longer for spin- $\frac{1}{2}$ species like ^{129}Xe or ^3He , so some 10^{21} highly polarized spins can be produced. The polarization is independent of the magnetic field. With more powerful tunable lasers, for example the AVLIS lasers developed for isotope separation at Lawrence Livermore National Laboratory in California, it would be possible to produce many grams of solid ^{129}Xe with nearly complete nuclear polarization.

2 OPTICAL PUMPING OF ALKALI VAPORS

Although all of the alkali metals have vapors suitable for spin exchange polarization of noble gas nuclei, rubidium is often chosen since it can be readily vaporized at modest temperatures where chemical attack on the glass container is not a problem. The $7947\text{ }\text{\AA}$ resonance line lies in a region where tunable dye lasers, titanium sapphire lasers and gallium aluminum arsenide

Figure 1 A typical experimental arrangement for spin exchange optical pumping to produce high nuclear spin polarization of noble gas nuclei

injection lasers can be used as intense light sources. It is also possible to use incoherent light from a resonance lamp for the optical pumping. A typical experimental arrangement is sketched in Figure 1. Not shown is the source of the static magnetic field B , which is often only a few ten-thousandths of a tesla, produced by Helmholtz coils and designed to prevent the spin depolarization by stray 60 Hz fields or the ambient field of the Earth. A simple oven is used to keep the cell at a constant temperature, usually greater than 80°C and less than 150°C . This ensures that the saturated vapor pressure of a few droplets of Rb metal in the cell is adequate. The number density of Rb atoms is typically $10^{11} - 10^{14} \text{ atoms cm}^{-3}$. More intense pumping light is needed to handle the higher number densities. The sample cell also contains the noble gas that is to be polarized by spin exchange and a chemically inert quenching gas, normally nitrogen, to prevent reradiation of light from the excited atoms. Since the reradiated light would be nearly unpolarized and can be absorbed by the Rb atoms, it would optically *depump* the atoms. The damage done by the reradiated photons becomes more severe at high Rb vapor densities, where the reradiated photon can be scattered several times and depolarize several atoms before escaping from the cell.

The mechanism for optical pumping is shown in Figure 2. We consider an imaginary alkali atom for which the nuclear spin is zero. All real alkali atoms have nonzero nuclear spins, but the basic mechanisms of optical pumping and spin exchange are qualitatively similar. Circularly polarized D_1 resonance light is incident on the atoms. The light can excite the atoms from the $^2S_{1/2}$ ground state into the $^2P_{1/2}$ first excited state. In both the ground state and the excited state, the electronic angular momentum of the atom can point up or down. This is represented by two Zeeman sublevels, which are split by their respective Larmor frequencies when the atom is in an external magnetic field. Since the atom must absorb both the energy and the spin angular momentum of the photon, transitions are only possible from the spin-down ground state sublevel to the spin-up excited state sublevel. The noble gas and the quenching gas collisionally transfer atoms between the sublevels of the excited state. When a quenching collision finally deexcites the atom, both ground state sublevels will be repopulated with nearly equal probability. Since the atom had $-\frac{1}{2}$ units of spin angular momentum before absorbing

Figure 2 Optical and nonradiative transitions involved in optical pumping of an alkali metal vapor at high optical density

the photon and 0 units of spin angular momentum after being quenched from the excited state, each absorbed photon deposits $\frac{1}{2}$ a unit of spin angular momentum in the vapor.

Even though the alkali vapor is often many optical depths thick, intense circularly polarized laser light can still illuminate most of the cell,¹⁶ as indicated in Figure 1. In the illuminated part of the cell, most of the alkali metal atoms are pumped into the nonabsorbing $+\frac{1}{2}$ sublevel of the ground state, and the spin polarization is nearly 100%. In the dark volume where no light penetrates, the alkali metal spin polarization is nearly zero, but some small spin polarization may be maintained by spin exchange with the polarized nuclei of the noble gas. Because of its long relaxation time, the spin polarization of the noble gas is nearly the same throughout the cell. The boundary between the illuminated and dark volumes of the cell is about one optical depth thick. In a well-designed system, the gas composition, the cell temperature, and the laser intensity are matched to ensure that most of the cell is illuminated.

3 SPIN EXCHANGE WITH NOBLE GAS NUCLEI

The transfer of angular momentum from the electron spin S of the alkali atom to the nuclear spin I of a noble gas atom during a collision is mediated by the Fermi contact interaction

$$\alpha \mathbf{S} \cdot \mathbf{I} \quad (1)$$

The coupling coefficient is given by the Fermi–Segré formula¹⁷

$$\alpha = \frac{16\pi}{3} \frac{\mu_B \mu_I}{I} |\eta \psi_0(R)|^2 \quad (2)$$

Here μ_B is the Bohr magneton, μ_I is the magnetic moment of the noble gas nucleus, and $\psi_0(R)$ is the value of the valence electron wave function of a free alkali metal atom at a distance R from the nucleus. Because the electron of the alkali atom is sucked into the attractive core of the noble gas

Figure 3 Spin exchange through the formation of van der Waals molecules (a) and in binary collisions (b)

atom, the valence electron wave function $\psi(R)$ is larger by an enhancement factor η than it would be if the xenon atom were not there. Approximate values for the enhancement factors for He, Ne, Ar, Kr, Xe, and Rn are^{18,19} -9.5, 15, -21, 35, -50, and 63, respectively.

As indicated in Figure 3, spin exchange from the alkali metal electron to the nucleus of the noble gas can occur either in a three-body collision [Figure 3(a)], for which a third body carries away the binding energy of the van der Waals molecule that is formed, or in a simple binary collision [Figure 3(b)]. The main observable difference between the two types of collision is that the relaxation and spin transfer caused by the van der Waals molecules, while extremely efficient, can be suppressed with external magnetic fields of a few hundredths to a few tenths of a tesla. The relaxation due to binary collisions is hardly affected by magnetic fields which are readily available in the laboratory.¹⁵ The relaxation due to van der Waals molecules also depends nonlinearly on the gas pressures in the cell.¹⁵ The three-body collisions can account for much of the spin exchange for the heavier noble gases, namely, Kr, Xe, or Rn, but binary collisions are the dominant spin exchange mechanism for the light gases He and Ne, which have particularly weak van der Waals wells with alkali metal atoms.

Bernheim²⁰ first pointed out that a large fraction of the spin angular momentum S of the alkali metal atoms is lost to the rotational angular momentum N of the alkali metal atom and its collisional partner through the spin-rotation interaction

$$\gamma S \cdot N \quad (3)$$

In close analogy to the Fermi-Segré formula, equation (2), the coupling constant for the heavier alkali metal atoms is given by²¹

$$\gamma = \frac{mG}{MR} \frac{d|\psi_0(R)|^2}{dR} \quad (4)$$

where m is the electron mass and M is the reduced mass of the alkali metal atom paired with the noble gas atom. Approximate

values, in units of MHz cm^5 , of the spin-rotation coupling factors G are 2.4×10^{-4} , 2.8×10^{-3} , 0.25, 1.5, 6.0, and 30 for He, Ne, Ar, Kr, Xe, and Rn, respectively.^{21,22}

The fraction of angular momentum that is transferred to the nucleus of the noble gas is

$$\epsilon = \frac{\alpha^2}{\frac{4}{3}(\gamma N)^2 + \alpha^2} \quad (5)$$

For example,¹⁹ for the pair ^{129}Xe Rb, the root mean square values of the coupling coefficients are $\alpha/h = 38 \text{ MHz}$ and $\gamma N/h = 121 \text{ MHz}$, so the efficiency of spin exchange would be about 4%; that is, $1/\eta = 25$ photons are needed to produce each fully polarized ^{129}Xe nuclear spin.

4 RELAXATION MECHANISMS FOR THE ALKALI ATOMS

The amount of nuclear spin polarization that can be accumulated by spin exchange optical pumping is limited by the loss of spin angular momentum through relaxation mechanisms. We have already discussed the important spin-rotation interaction, equation (3), which causes a loss of electronic spin angular momentum S to rotational angular momentum N during collisions of the alkali atom with the noble gas atom or with the quenching gas molecules.

The spin exchange probability per collision is small for the lighter noble gases ^3He and ^{21}Ne because the enhancement factor η of equation (2) is small and because there are few sticking collisions like those of Figure 3(a). In these cases, it is advantageous to operate with as high a number density of alkali metal atoms as possible to speed up the spin exchange. At high densities, there are frequent spin exchange collisions between alkali metal atoms A and B:

The up and down arrows indicate the orientations of the electron spins. The cross sections for electron-electron spin exchange collisions¹² are on the order of 10^{-14} cm^2 , so the exchange rates can be on the order of 10^4 s^{-1} at alkali metal atomic number densities of 10^{14} cm^{-3} . Electron-electron exchange is much faster than any other spin relaxation rate, but since such collisions conserve the total spin of the vapor, they do not interfere with the polarization of noble gas nuclei. Electron spin exchange does broaden the spin resonance lines of the alkali vapor, and the broadening can be used to measure the vapor density.²³

Unfortunately, a small fraction of the collisions between alkali metal atoms transfer spin angular momentum to the translational angular momentum of the vapor. Bhaskar et al.²⁴ have shown that for cesium atoms A and B, spin-destroying collisions of the form

occur at about 1% of the rate of spin exchange collisions, equation (6). The basic physics of the interaction, equation (7), has not been studied in detail, but it must be related in part

to the physics of the spin–rotation interaction, equation (3). Knize²⁵ has shown that the rate of spin-destroying collisions, equation (7), is less for the lighter alkali metal atoms Rb and K than for Cs. For the important case of ^3He gas, in which the electron–nucleus spin exchange interaction, equation (1), and the spin–rotation interaction, equation (2), are both very small, it is the spin-destroying collisions, equation (7), between alkali metal atoms that set the practical upper limit on the alkali metal vapor pressure and on the speed with which the ^3He can be polarized.^{1,2}

The walls of ordinary glass or metal containers completely depolarize the spin of an alkali atom that hits them. However, alkali atoms can bounce off walls coated with paraffin or silicone²⁶ with little loss of angular momentum. Experimental conditions for spin exchange polarization of noble gas nuclei are usually such that losses due to the interactions, equations (3) and (7), are much larger than any losses due to wall interactions of the alkali metal atoms.

5 RELAXATION MECHANISMS FOR THE NOBLE GAS ATOMS

The spin exchange interaction, equation (1), can be an important source of relaxation for noble gas nuclei when the alkali metal atoms have a high density and are nearly unpolarized, as they are when no pumping light is present. Studies¹⁵ of this type of relaxation have been the main experimental source of information about the magnitude of the spin exchange coupling coefficient α of equation (1) and also of the spin–rotation coupling constant γ of equation (3).

When the density of alkali metal atoms is small enough, various intrinsic mechanisms can cause the noble gas atoms to relax. The dipole–dipole interaction between the magnetic moments of ^3He nuclei can be a limiting relaxation mechanism in high-density helium gas,²⁷ one of the few practical situation where this plausible but usually ineffectual interaction actually dominates the longitudinal relaxation rates. The observed longitudinal relaxation of the spin- $\frac{1}{2}$ nuclei of ^{129}Xe in high-pressure xenon gas is much too fast to be due to the magnetic dipole–dipole interaction, and Torrey²⁸ showed that the relaxation is due to the nuclear spin–rotation interaction

$$\gamma I \cdot N \quad (8)$$

For the spin- $\frac{3}{2}$ nucleus of ^{131}Xe high-pressure gases, and presumably for other noble gas nuclei with electric quadrupole moments. Brinkmann et al.²⁹ have shown that the observed relaxation is due to torques on the nuclear quadrupole from field gradients induced during the collisions.

Since the noble gas atoms diffuse readily in the gas phase and the optical pumping is often done at small magnetic fields (on the order of a few ten thousandths of a tesla), residual inhomogeneities of the magnetic field can be a serious source of relaxation. At sufficiently high gas pressures, the longitudinal relaxation rate due to field inhomogeneities is³⁰

$$\frac{1}{T_1} = D \frac{|\nabla B_x|^2 + |\nabla B_y|^2}{B_0^2} \quad (9)$$

where B_x and B_y are the components of the inhomogeneous field along the x and y axes, at right-angles to the mean

field B_0 , which defines the z axis of the coordinate system. The diffusion coefficient of the noble gas in the cell is D . Cates et al.³¹ have investigated relaxation of the transverse spin polarization in inhomogeneous fields and also transverse and longitudinal spin relaxation at very low pressures where motional narrowing and the dimensions and shape of the cell are important. In practice, it is not difficult to make the field inhomogeneities small enough to contribute a negligible amount to spin relaxation.

Spin depolarization at the walls is an important consideration for the nuclei of the noble gases. Fitzsimmons et al.³² showed that very long longitudinal relaxation times T_1 can be obtained for ^3He in aluminosilicate glass cells, particularly Corning 1720 glass. Much shorter relaxation times are observed for borosilicate glass or quartz. The reason seems to be that the small ^3He atoms diffuse into the rather loose SiO_2 lattice structure of borosilicate or quartz, but are unable to penetrate the much tighter aluminosilicate network. Although most of the work of Fitzsimmons et al.³² was done in metal-free cells, aluminosilicate glass cells that also contain droplets of alkali metal^{1,2} have proven to be excellent containers for ^3He . Relaxation times of many hours can be obtained for well-prepared cells of this kind.

The situation is less clear for the heavier noble gases like ^{129}Xe , which cannot penetrate the SiO_2 lattice structure of borosilicate or quartz. Here most of the interactions seem to occur on the glass surface. The nature of the glass surface in sample cells exposed to the vapors of alkali metals is very poorly understood at present. Relaxation times of a minute or less are usually observed for ^{129}Xe in newly manufactured glass cells. Over a period of some days, glass cells develop longer and longer relaxation times as they ‘cure’. Well-cured borosilicate glass cells have relaxation times of about one hour for ^{129}Xe . Neither quartz nor aluminosilicate cells seems to undergo ‘curing’.

For noble gases like ^{21}Ne ($I = \frac{3}{2}$), ^{83}Kr ($I = \frac{9}{2}$), and ^{131}Xe ($I = \frac{3}{2}$), the wall relaxation is normally dominated by nuclear quadrupole interactions,^{33,34} and is much shorter than for spin- $\frac{1}{2}$ nuclei, which have no quadrupole moment. Substantially longer spin relaxation times for noble gases with nuclear quadrupole moments are observed if a few hundred Pa of hydrogen gas are included in the cell before it is sealed off. The hydrogen slowly reacts with alkali metal on the glass wall to form alkali hydride salt crystals.

Extreme motional narrowing is often observed in cells with relatively low-pressure gas. Nuclei with quadrupole moments interact with the ensemble-averaged electric field gradient of the inner wall of asymmetric cells like that of Figure 4(a). The Zeeman degeneracy of the magnetic sublevels is lifted by the surface-averaged quadrupole interaction, as sketched in Figure 4(b). The transverse relaxation transients exhibit beats, as indicated in Figure 4(c), and the Fourier transform of the relaxation transient gives the energy intervals of the spin, as sketched in Figure 4(d).

Silicone wall coatings like ‘Surfasil’ from Pierce Chemical can greatly lengthen the relaxation times for the spin- $\frac{1}{2}$ nuclei of ^{129}Xe in glass cells,³⁵ but they speed up³⁶ the relaxation of the spin- $\frac{3}{2}$ nuclei of ^{131}Xe . Understanding and controlling wall interactions is the most pressing problem outstanding for artificial polarization of noble gas nuclei by spin exchange with optically pumped alkali metal atoms.

Figure 4 Beats in the free induction decay of nuclei with spins greater than $\frac{1}{2}$ due to quadrupolar interactions on the walls of an asymmetric cell

1 INTRODUCTION

The sensitivity for detection of the bulk magnetization induced in a collection of nuclear spins by an externally applied magnetic field $\mathbf{B}_0$ is proportional to the magnetogyric ratio γ of the nuclei in question and their natural abundance. If the sensitivity is poor or the amount of material (usually a chemical compound) available for analysis is small then the signal strength recorded following a standard pulse-and-collect experiment may be insufficient relative to the thermal noise of receiver systems, rf coil, preamplifier, etc. to analyze the spectrum. Consequently, signal averaging to improve spectral quality may be necessary. The signal-to-noise (S/N) ratio will improve proportionally to $\sqrt{N}$, where N is the number of acquisitions or repetitions of the sequences of rf pulses used to generate the free induction decay (FID) from the nuclei of interest. If signal averaging is a requirement to obtain a desired S/N, the interrelationship of the repetition time of the experiment (TR) relative to the spin–lattice relaxation time T_1 of the nuclei in question becomes an important consideration. Based upon this consideration, it is possible to calculate an optimum for the flip angle (the Ernst angle) for use in a multi-acquisition single pulse experiment so as to ensure that the S/N per acquisition is maximized.

^1H is a nucleus of high natural abundance and large γ . In general, for organic molecules in solution, the T_1 values are of the order of a few seconds or shorter, allowing the acquisition of high quality spectra from solutions having a concentration of $\leq 10\ \mu\text{M}$ in a relatively short time period, usually minutes. ^1H NMR spectroscopy, for these and other reasons, is one of the most important techniques for the structure determination of organic and biorganic molecules.

NMR detection of so-called heteronuclei (^{13}C , ^{15}N , ^{29}Si , ^{119}Sn , and others) was recognized in early studies using magnetic resonance methods as having great potential for chemical structure determination. ^{13}C and ^{15}N are the most important; both nuclei have low natural abundance and greatly reduced γ values relative to ^1H . Although T_1 values for ^{13}C are as short as those for ^1H , ^{15}N can have long T_1 values in many structurally interesting environments. In addition, γ for ^{15}N is negative, and thus depends on the relative values of the ^{15}N spin–lattice relaxation processes operating (^1H – ^{15}N

dipole–dipole, relaxation arising from unpaired electrons present in paramagnetic species, etc.). Therefore nuclear Overhauser enhancement (NOE) of ^{15}N signals consequent on the application of a ^1H decoupling field to remove ^1H – ^{15}N scalar couplings can have a deleterious effect on the ^{15}N signal intensity. If the extreme narrowing limit is applicable, $\omega\tau \ll 1$, where ω is the resonance frequency in rad s^{-1} and τ the correlation time for the relaxation process, the maximum NOE value arising from ^1H dipolar coupling is $1 + \gamma_{\text{H}}/2\gamma_{\text{X}}$, where X is the heteronucleus.¹ For ^{13}C , the maximum NOE is 2.98, but for ^{15}N it is -3.93 .

The central theme of this article is polarization transfer methods.² The discussion will be limited to liquid state studies, where the only mechanism available to induce the transfer is via the scalar interaction $\mathbf{I} \cdot \mathbf{S}$, where $\mathbf{I}$ and $\mathbf{S}$ are the coupled spin partners having coupling constant J (in Hz: $2\pi J$ in rad s^{-1}). In the following discussion, $\mathbf{S}$ refers to the spin having the larger $|\gamma_{\text{S}}| > |\gamma_{\text{I}}|$. (Originally, $\mathbf{I}$ and $\mathbf{S}$ were identified with ‘insensitive’ and ‘sensitive’, respectively. This article has been written with this assignment in mind—other authors³ have inverted this definition.) $\mathbf{S}$ is usually the ^1H spin. The basic idea is to transfer polarization from $\mathbf{S}$ to $\mathbf{I}$ yielding a signal intensity boost that depends upon the number of $\mathbf{S}$ spins scalar-coupled to $\mathbf{I}$ by an amount $\geq |\gamma_{\text{S}}/\gamma_{\text{I}}|$; an added bonus is that the experimental acquisition conditions now depend upon the $\mathbf{S}$ -spin T_1 values. This is a particularly desirable feature for ^{15}N NMR. It should be clearly understood that the magnetization giving rise to the $\mathbf{I}$ polarization transfer signal is in no way related to the natural magnetization induced into the $\mathbf{I}$ spins in the sample by the application of $\mathbf{B}_0$. (Below, the symbol $\mathbf{K}^{\text{C}}$ is used to represent the natural magnetization induced into ^{13}C spins by the applied magnetic field.)

Before polarization transfer pulses sequences are discussed in detail, some simple ideas involving product operator algebra will be introduced. (Note that various constructions of product operator algebra have been published.^{2,4})

2 PRODUCT OPERATOR ALGEBRA FOR IS_n SPIN SYSTEMS

In order best to summarize the ideas behind these experiments, it is useful to concentrate the discussion where appropriate on the cases $n = 1$ and $n = 2$ and allow the interested reader to investigate the general case. It is assumed that the IS_n spin system is weakly coupled. This one assumption, clearly valid for CH_n and NH_n spin systems, allows enormous simplification of the mathematical description of the effect of polarization transfer pulse trains on the available spin coherences.⁴

Fact 1. The initial spin coherence for IS_n can be represented as $I_z(U^{\text{S}})^n$ and n states of the form $U^{\text{I}}S_z(U^{\text{S}})^{n-1}$, where I_z and S_z are the z components of the $\mathbf{I}$ and $\mathbf{S}$ spin angular momenta, respectively, and U^{S} and U^{I} are unit operators for each of the remaining spins, proportional to the sum of the respective populations α and β . As opposed to other constructions of product operator algebra,⁴ the unit operators are retained, since, as shown below, they readily allow the prediction of the appearance of the spectrum. For $n = 1$, the initial spin coherences are therefore I_zU^{S} and $U^{\text{I}}S_z$, while for $n = 2$, they are $I_z(U^{\text{S}})^2$ and two states of the form $U^{\text{I}}S_zU^{\text{S}}$.

2 POLARIZATION TRANSFER EXPERIMENTS VIA SCALAR COUPLING IN LIQUIDS

Table 1 Summary of the Effect of Pulses and Periods of Free Precession on the Operator Basis S_x, S_y, S_z^a

$\frac{1}{2}\pi(x)$	$\frac{1}{2}\pi(y)$	$\frac{1}{2}\pi(-x)$	$\frac{1}{2}\pi(-y)$
$S_x \rightarrow S_x$	$S_x \rightarrow S_z$	$S_x \rightarrow S_x$	$S_x \rightarrow -S_z$
$S_y \rightarrow -S_z$	$S_y \rightarrow S_y$	$S_y \rightarrow S_z$	$S_y \rightarrow S_y$
$S_z \rightarrow S_y$	$S_z \rightarrow -S_x$	$S_z \rightarrow -S_y$	$S_z \rightarrow S_x$

The general case becomes, for a $\frac{1}{2}\pi(\Psi)$ pulse,
 $S_x \rightarrow S_x \cos^2 \Psi + S_y \sin \Psi \cos \Psi + S_z \sin \Psi$
 $S_y \rightarrow S_y \sin^2 \Psi + S_x \cos \Psi \sin \Psi - S_z \cos \Psi$
 $S_z \rightarrow S_y \cos \Psi + S_x \sin \Psi$

Periods of free precession, free-precession time τ (on resonance) are analyzed using
 $U^S \rightarrow U^S \cos(\pi J \tau) - iS_z \sin(\pi J \tau)$
 $S_z \rightarrow S_z \cos(\pi J \tau) - iU^S \sin(\pi J \tau)$

Axes after evolutionary period are defined as^b
 $iS_y \equiv S_x, -S_y \equiv iS_x, -iS_y \equiv -S_x, S_y \equiv -iS_x$

^a U^S is unaffected by any pulse.

^bFollowing a period of free precession, the axis definitions must be made before the effect of any further pulse is considered. For example, consider $I_x U^S \rightarrow I_x [U^S \cos(\pi J \tau) - iS_z \sin(\pi J \tau)]$. This must be rewritten as $I_x U^S \cos(\pi J \tau) + I_y S_z \sin(\pi J \tau)$ before the effect of any further I -spin rf pulses can be determined.

Fact 2. A Cartesian basis is chosen to model pulse rotations. The effect of rotation by a $\frac{1}{2}\pi(i)$ pulse (where i is the phase of the rf pulse) on the basis set (S_x, S_y, S_z) is given in Table 1.

Fact 3. During detection, the z -eigenstate probabilities of the coupled spin partner determine the appearance of the spectrum. For example, application of a $\frac{1}{2}\pi(x)$ pulse to the I spins in an IS_2 spin system causes the change

$$I_z(U^S)^2 \rightarrow I_y(U^S)^2 \quad (1)$$

If $I_y(U^S)^2$ is now detected, a 1:2:1 multiplet is clearly observed as $I_y(U^S)^2 \equiv I_y(\alpha_S^2 + 2\alpha_S\beta_S + \beta_S^2)$. If a series of rf pulses and timing periods are applied to generate the spin coherence $I_y U^S S_z$, for example, and this is now detected, a 1:0:-1 multiplet is observed as $I_y U^S S_z \equiv I_y(\alpha_S + \beta_S)(\alpha_S - \beta_S) = I_y(\alpha_S^2 - \beta_S^2)$. (The instantaneous emf induced in the receiver coil from this spin coherence is zero, but during the acquisition time t_2 , a signal is induced, and the multiple structure observed in the frequency domain is the Fourier transform of this signal.) This illustrates the advantage of retaining the unit operators in describing the effects of a pulse sequence on the spin coherences at the start of, during, and at the detection stages of the pulse train. The linkage of the spin coherences at each stage of a pulse sequence following an rf pulse or timing period is called a coherence pathway.⁵

Fact 4. To calculate the time evolutions of the Cartesian spin operators S_x and S_y , it is more convenient to treat such precessional effects using a different basis system. Define $S_+ = \frac{1}{2}(S_x + iS_y)$ and $S_- = \frac{1}{2}(S_x - iS_y)$. Then, with these transformations, $S_x = \text{Re } S_+ = \text{Re } S_-$ and $S_y = \text{Im } S_+ = -\text{Im } S_-$. The time evolutions of S_+ and S_- are

$$\left. \begin{aligned} S_+(\tau) &= S_+ \exp(i\beta) \\ S_-(\tau) &= S_- \exp(-i\beta) \end{aligned} \right\} \quad (2)$$

where β is the angle (in rad) in the rotating frame through which the transverse magnetization has precessed. It can

be readily shown that if scalar coupling is the only effect operating (that is, π pulses have been inserted at the appropriate timing points during the pulse sequence in order to eliminate precessional effects arising from chemical shift offset) then U^S and S_z are modified as follows:

$$U^S \rightarrow U^S \cos(\pi J \tau) - iS_z \sin(\pi J \tau) \quad (3)$$

$$S_z \rightarrow S_z \cos(\pi J \tau) - iU^S \sin(\pi J \tau) \quad (4)$$

These equations are the key to understanding polarization transfer pulse sequences in liquids; consequently, it is useful to follow their derivation in some detail. Within the spirit of this article, only an IS spin-coupled spin system is considered.

Suppose the S spins receive a broadband $\frac{1}{2}\pi(x)$ rf pulse; the initial spin coherence $U^I S_z$ is modified: $U^I S_z \rightarrow U^I S_y \equiv (\alpha_I + \beta_I)S_y$. Acquisition of the signal at this point yields the expected 1:1 doublet. Suppose the magnetization is allowed to precess before acquisition begins. How are the changes in the spin coherences calculated? $\alpha_I S_y$ and $\beta_I S_y$ will both precess with a period of $1/2J$ (in s), but their angular velocity will be $\pm\pi J$ (in rad s⁻¹), respectively. Precessional effects arising owing to chemical offset are neglected. If τ is set such that $\alpha_I S_y$ and $\beta_I S_y$ have precessed through angles of $\pm\frac{1}{2}\pi$, respectively, then $\alpha_I S_y$ will be changed to $-\alpha_I S_x$ and $\beta_I S_y$ to $\beta_I S_x$. The precessional time required to induce this change is given by $\pi J \tau = \frac{1}{2}\pi$ or $\tau = 1/2J$. These changes are shown diagrammatically in Figure 1. The effect of such a time period is thus

$$U^I S_y \equiv (\alpha_I + \beta_I)S_y \xrightarrow{1/2J} -\alpha_I S_x + \beta_I S_x \quad (5)$$

$(-\alpha_I S_x + \beta_I S_x)$ may be written as $-(\alpha_I - \beta_I)S_x$. Of course $(\alpha_I - \beta_I)$ is proportional to I_z , and so the effect of the $1/2J$ time period may be summarized as follows:

$$U^I S_y \xrightarrow{\frac{1}{2}\pi(S_x)} U^I S_y \xrightarrow{1/2J} -I_z S_x \quad (6)$$

Figure 1 Vector diagrams illustrating the precessional effects following the pulse sequence $\frac{1}{2}\pi(S, x) - 1/2J$ – applied to an IS spin system. The pulse sequence shows how magnetization is generated in a coupled spin partner via precession. This magnetization will wax and wane as the precessional effects continue in the transverse plane

Thus, following the $1/2J$ time period, magnetization is induced in the scalar-coupled spin partner, and of course I_z is observable (see below) by the application of an rf pulse to the I magnetization. Note that the magnetization induced in the sample by this process is quite independent of the bulk magnetization induced in the I spins by the static magnetic field; I_z induced by the polarization transfer process depends on the S population difference. If τ differs from $1/2J$ then the derivation of equations 3 and 4 follows easily from the fact that

$$\left. \begin{aligned} S_y(\tau) &= S_y \cos \beta + S_x \sin \beta \\ S_x(\tau) &= S_x \cos \beta - S_y \sin \beta \end{aligned} \right\} \quad (7)$$

3 POLARIZATION TRANSFER PROCESS

3.1 The SPT Experiment

The selective population transfer (SPT) experiments⁶ were the forerunners of the general pulse sequence procedures used to transfer polarization nonselectively. Here ‘nonselectively’ implies the transfer of polarization between, for example, ^1H and scalar-coupled ^{13}C nuclei irrespective of the ^1H or ^{13}C resonance frequency relative to the frequencies of the rf pulses.

For the $^1\text{H} \rightarrow ^{13}\text{C}$ SPI polarization transfer, the coherence pathway may be written as

$$U^C S_z^H (U^H)^{n-1} \propto (\alpha_C + \beta_C) S_z^H (U^H)^{n-1} \xrightarrow[\text{selective}]{\pi(H)_{\alpha_C}} (-\alpha_C + \beta_C) S_z^H (U^H)^{n-1} \propto S_z^C S_z^H (U^H)^{n-1} \quad (8)$$

where now S_z^H and S_z^C represent the ^1H and ^{13}C magnetizations. $\pi(H)_{\alpha_C}$ is a selective inversion pulse on the low-frequency ^{13}C satellite of a particular ^1H resonance. Of course, $S_z^C S_z^H (U^H)^{n-1}$ does not give rise to any observable signal. However, if a hard non-selective $\frac{1}{2}\pi(x)$ pulse is

now applied to the ^{13}C spins and ^{13}C acquisition is commenced immediately then the observed signal arises from a combination of the natural ^{13}C magnetization originating from $K_z^C (U^H)^n \rightarrow K_y^C (U^H)^n$ and from acquisition of $S_z^C S_z^H (U^H)^{n-1} \rightarrow S_y^C S_z^H (U^H)^{n-1}$. (See the comment on data acquisition above regarding how $S_y^C S_z^H (U^H)^{n-1}$ gives rise to the observable original.) Different symbols have been used for the two different components of the ^{13}C magnetization to emphasize the fact that the total ^{13}C magnetization observed originates from two different sources; $S_y^C / K_y^C = \gamma_H / \gamma_C$.

If $n = 1$ then the observed signal originates from $K_y^C U^H + S_y^C S_z^H$. Given that $\gamma_H / \gamma_C \approx 4$, the observed signal appears as a 5:–3 or –3:5 doublet, depending upon which ^{13}C satellite is inverted in the ^1H spectrum. If $n = 2$ and two acquisitions are acquired, with the $\pi(H)$ selective pulse being applied alternately to each ^{13}C satellite and the phase of the receiver being inverted for each acquisition, then the overall signal can be viewed as arising from the total coherence given by $[K_y^C (U^H)^2 + S_y^C S_z^H U^H] - [K_y^C (U^H)^2 - S_y^C S_z^H U^H] = 2S_y^C S_z^H U^H$; as explained before, this yields a 1:0:–1 ‘triplet’. Noting that the natural magnetization is present, (here represented by a different symbol K_y^C) and that it can always be removed by phase cycling, in subsequent discussion any signal arising from it will be neglected.

3.2 The INEPT Pulse Sequence

The first nonselective polarization transfer technique was developed by Morris and Freeman.⁷ Its application to $^1\text{H} \rightarrow ^{13}\text{C}$ polarization transfer will be illustrated. For the double on-resonance case, the pulse sequence is

$$\frac{\pi}{2}(H, x) - \frac{1}{2J} - \frac{\pi}{2}(H, \pm y) \frac{\pi}{2}(C, x) - \text{Acquire } ^{13}\text{C} \quad (9)$$

where ‘Acquire ^{13}C ’ means to turn the ^{13}C receiver on (the form of the signal observed is governed by Fact 3 above) and $\pm y$ means that the phase of the last ^1H pulse is alternated (with receiver phase alternation concurrently) to remove signal arising from the natural ^{13}C magnetization. The coherence pathway may be summarized as follows:

$$U^C S_z^H (U^H)^{n-1} \xrightarrow{\frac{1}{2}\pi(H, x)} U^C S_y^H (U^H)^{n-1} \xrightarrow{1/2J} -S_z^C S_x^H (U^H)^{n-1} \xrightarrow{\frac{1}{2}\pi(H, y)} -S_z^C S_z^H (U^H)^{n-1} \xrightarrow{\frac{1}{2}\pi(C, x)} -S_y^C S_z^H (U^H)^{n-1} \quad (10)$$

It is clear that on data acquisition, for $n = 1$, a 1:–1 doublet will be observed; for $n = 2$, a 1:0:–1 triplet will be observed; and for $n = 3$, a 1:1:–1:–1 quartet will be observed. These multiplets will all be enhanced relative to that arising from the natural magnetization eliminated by the pulse sequence, because its phase does not depend upon the phase of the second $\frac{1}{2}\pi(H, y)$ pulse. It is also obvious why a y -phased pulse is required at this timing point, since it acts on a spin coherence of the form $-S_z^C S_x^H (U^H)^{n-1}$. Clearly, the rules introduced above allow a simple analysis of a pulse sequence in terms of how the final spectrum appears and what the phase of each

of the rf pulses is at each point in a pulse sequence. Off-resonance effects (that is, nonselectivity) can be eliminated by breaking the $1/2J$ timing period by two π pulses as follows: $-1/4J - \pi(C)\pi(H) - 1/4J -$. The application of two π pulses is required in order to remove chemical shift offset effects for ^1H and to ensure that S_z^C is generated by the precession. If $\pi(H)$ were applied without the $\pi(C)$ pulse (remember that during the first timing period only ^1H magnetization is in the transverse plane) then the transverse magnetization giving rise to the ^{13}C satellites in the ^1H spectrum would simply rephase (a spin echo) along the y axis after the second $1/4J$ time period. The $\pi(C)$ ensures that this does not occur by inverting the ^{13}C spin states.

It is clear that the detectable ^{13}C coherence following the INEPT pulse sequence remains correlated with S_z^H . As noted, if the ^{13}C magnetization is now detected, the individual multiplet resonances phase alternate. Consequently, if broadband proton decoupling is applied concurrently with ^{13}C data acquisition then all detectable signal is destroyed. To overcome this problem, delayed acquisition (by an amount Δ) is employed.⁸ The effect of this added time (implemented as $-\frac{1}{2}\Delta - \pi(C)\pi(H) - \frac{1}{2}\Delta -$ to eliminate chemical shift offset effects) can be calculated using the results in Table 1 as follows:

$$-S_y^C S_z^H (U^H)^{n-1} \longrightarrow_{\Delta} S_x^C (U^H)^n \sin(\pi J \Delta) \times \cos^{n-1}(\pi J \Delta) + \dots \quad (11)$$

Proton decoupling eliminates all terms except the first. For interesting values of $n = 1, 2$, or 3 , it can be shown that the signal intensity is modulated as shown in Table 2. It is clear from this analysis how the INEPT pulse sequence can be used to distinguish the number of protons scalar-coupled to a particular carbon nucleus by observing a proton-decoupled ^{13}C spectrum. This experimental method is very valuable in structural organic chemistry, since it allows the chemist to ‘count’ the number of protons attached to a particular carbon center.

For n protons scalar-coupled to a nucleus I , it has been shown⁹ that the ^1H -decoupled enhancement E_d following the INEPT pulse sequence is given by

$$E_d = n(\gamma_H/\gamma_I) \sin(\pi J \Delta) \cos^{n-1}(\pi J \Delta) \quad (12)$$

The first maximum of this function occurs at Δ_{opt} , where

$$\Delta_{\text{opt}} = (\pi J)^{-1} \arcsin(1/\sqrt{n}) \quad (13)$$

Table 2 Summary of the Effects of Selected Time Periods for Different Protonated ^{13}C Resonances Following the INEPT Pulse Sequence⁸

Group	Modulation function	Comment
^{13}CH	$\sin(\pi J \Delta)$	Maximum at $\Delta = 1/2J$
$^{13}\text{CH}_2$	$\frac{1}{2} \sin(2\pi J \Delta)$	Maximum at $\Delta = 1/4J$ Zero at $\Delta = 1/2J$ Maximum but phase-inverted at $\Delta = 3/4J$
$^{13}\text{CH}_3$	$\sin(\pi J \Delta) \cos^2(\pi J \Delta)$	Maximum at $\Delta = 0.196/J$ Zero at $\Delta = 1/2J$ No phase change at $\Delta = 3/4J$

giving the optimum decoupled enhancement factor E_{dopt} :

$$E_{\text{dopt}} = \frac{\gamma_H}{\gamma_I} \sqrt{n} \left(1 - \frac{1}{n}\right)^{(n-1)/2} \quad (14)$$

Table 3 shows that E_{dopt} increases as n increases. $E_{\text{dopt}} = \gamma_H/\gamma_I$ for $n = 1, 2$, but it can exceed $2\gamma_H/\gamma_I$ for $n \geq 11$. Such behavior is significantly different from that observed for the NOE, which is independent of n , and large polarization transfer enhancements are possible for a variety of interesting systems having large n . Results obtained from ^{29}Si and ^{119}Sn NMR have confirmed the theoretical predictions noted above. Note that for ^{15}N NMR, the INEPT pulse sequence is an ideal measuring method compared with the conventional pulse-and-collect technique, since the complication of a negative NOE does not arise.

3.3 The DEPT Pulse Sequence

The basic ideas behind nonselective polarization transfer are clearly evident from analysis of the INEPT pulse sequence. However, the amount of polarization transfer depends upon J . If there are a range of J values for the same nucleus because structurally different chemical environments are present in the compound of interest then there will be a variability in the amount of polarization transfer for the different resonances using the INEPT technique. In addition, as a general guide, any multipulse sequence should use the minimum number of rf pulses to induce the desired result, thus reducing the effects of errors in rf pulse angle and phase. To reduce the J dependence (but not eliminate it) and to reduce the number of rf pulses employed to effect polarization transfer, the DEPT pulse sequence was developed.¹⁰ This is the series of rf pulses written and analyzed as follows for $^1\text{H} \rightarrow ^{13}\text{C}$ polarization transfer.

$$\begin{aligned} \frac{\pi}{2}(\text{H}, x) - \frac{1}{2J} - \frac{\pi}{2}(\text{C}, x)\pi(\text{H}) - \frac{1}{2J} - \theta(\text{H}, y)\pi(\text{C}) \\ - \frac{1}{2J} - \text{Acquire } ^{13}\text{C} \end{aligned} \quad (15)$$

$\theta(\text{H}, y)$ is a ^1H pulse applied along the y axis of the rotating frame such that the nutation angle is θ . Such a pulse causes the following rotations:

$$\left. \begin{aligned} S_x^H &\rightarrow S_z^H \sin \theta + S_x^H \cos \theta \\ S_y^H &\rightarrow +S_y^H \\ S_z^H &\rightarrow S_z^H \cos \theta - S_x^H \sin \theta \end{aligned} \right\} \quad (16)$$

Note that the pulse sequence can be broken into two overlapping halves. During the first half, only ^1H magnetization is in the transverse plane, thus requiring only one $\pi(\text{H})$ pulse to eliminate chemical shift offset effects; during the second half only ^{13}C magnetization is in the transverse plane, and consequently only one $\pi(\text{C})$ pulse is required. The number of π pulses compared with the INEPT sequence has thus been reduced by two. Also, multiplicity differences are, as shown below, differentiated by the application of different but specific values of the pulse angle θ . The timing periods are not changed, and so any variability in T_2 between different resonances is not a consideration, as would occur using the INEPT

Table 3 Values of Δ_{opt} to Give the Maximum Decoupled Enhancement E_{dopt} as a Function of the Number of Scalar-Coupled Protons⁹

n	1	2	3	4	6	8	9	12	15	18
$\Delta_{\text{opt}}/J^{-1}$	0.50	0.25	0.196	0.167	0.134	0.115	0.108	0.093	0.083	0.076
$E_{\text{dopt}}/(\gamma_{\text{H}}/\gamma_{\text{I}})$	1.0	1.0	1.155	1.299	1.553	1.772	1.873	2.147	2.389	2.610

pulse sequence as Δ is changed. As will become apparent, all multiples are enhanced, but since the multiplet structure arises from $S_y^{\text{C}}(U^{\text{H}})^n$, the spectral appearance is the same as that obtained using conventional pulse-and-collect technology.

Although some appreciation of how the INEPT pulse sequence operates can be obtained using simple spin vector diagrams,⁷ such an approach fails when applied to the DEPT experiment. The power of the product operator method in analyzing this pulse sequence is clearly evident. Consider first the case, $n = 1$ that is, for a CH group. The coherence pathway can be written as follows (neglecting chemical shift offset effects):

$$\begin{aligned}
 U^{\text{C}}S_z^{\text{H}} &\xrightarrow{\frac{1}{2}\pi(\text{H},x)} U^{\text{C}}S_y^{\text{H}} \xrightarrow{1/2J} -S_z^{\text{C}}S_x^{\text{H}} \xrightarrow{\frac{1}{2}\pi(\text{C},x)} -S_y^{\text{C}}S_x^{\text{H}} \\
 &\xrightarrow{1/2J} -S_y^{\text{C}}S_x^{\text{H}} \xrightarrow{\theta(\text{H},y)} -S_y^{\text{C}}(S_z^{\text{H}}\sin\theta + S_x^{\text{H}}\cos\theta) \\
 &\xrightarrow{1/2J} S_x^{\text{C}}U^{\text{H}}\sin\theta - S_y^{\text{C}}S_x^{\text{H}}\cos\theta
 \end{aligned} \quad (17)$$

Considering the end product of the pulse sequence, the only detectable magnetization arises from $S_x^{\text{C}}U^{\text{H}}\sin\theta$. This gives rise to an enhanced 1:1 ^{13}C doublet, whose intensity is modulated as $\sin\theta$; the maximum occurs when $\theta = \frac{1}{2}\pi$. The second term, $S_y^{\text{C}}S_x^{\text{H}}\cos\theta$, can be written, neglecting the θ dependence, as $-S_y^{\text{C}}S_x^{\text{H}} \equiv -(1/4i)(S_+^{\text{C}}S_+^{\text{H}} - S_-^{\text{C}}S_-^{\text{H}} + S_+^{\text{C}}S_-^{\text{H}} - S_-^{\text{C}}S_+^{\text{H}})$. The first two terms are known as double quantum coherence (in a z -eigenstate description, states separated by two quanta of energy, e.g. $|\alpha\alpha\rangle$ and $|\beta\beta\rangle$, can be connected) and the last two terms represent zero quantum coherence. No observable signal can result from the coherence $-S_y^{\text{C}}S_x^{\text{H}}\cos\theta$. As a general rule, observable signal arises when there is only one spin in the transverse plane.

Consider the case $n = 2$, that is, for a CH_2 group. The first $\frac{1}{2}\pi(\text{H},x)$ pulse acts on the spin coherence $U^{\text{C}}S_z^{\text{H}}U^{\text{H}}$, and the resulting changes induced by the first half of the pulse sequence can be summarized as follows:

$$\begin{aligned}
 U^{\text{C}}S_z^{\text{H}}U^{\text{H}} &\xrightarrow{\frac{1}{2}\pi(\text{H},x)} U^{\text{C}}S_y^{\text{H}}U^{\text{H}} \xrightarrow{1/2J} -S_z^{\text{C}}S_x^{\text{H}}U^{\text{H}} \\
 &\xrightarrow{\frac{1}{2}\pi(\text{C},x)} -S_y^{\text{C}}S_x^{\text{H}}U^{\text{H}}
 \end{aligned} \quad (18)$$

Because the ^{13}C J coupling is of course still acting, the second $1/2J$ time period induces the following change:

$$-S_y^{\text{C}}S_x^{\text{H}}U^{\text{H}} \xrightarrow{1/2J} S_x^{\text{C}}S_x^{\text{H}}S_z^{\text{H}} \quad (19)$$

As noted above, only single quantum terms can yield observable magnetization. Thus the only term of interest following the $\theta(\text{H}, y)$ pulse is

$$S_x^{\text{C}}S_x^{\text{H}}S_z^{\text{H}} \xrightarrow{\theta(\text{H},y)} S_x^{\text{C}}(S_z^{\text{H}})^2\sin\theta\cos\theta \quad (20)$$

Compared with the case, $n = 1$ the $\pi(\text{C})$ must invert the sign of this coherence if it is applied along the y axis, $S_x^{\text{C}} \xrightarrow{\pi(\text{C},y)} -S_x^{\text{C}}$,

or invert the sign of the coherence at the corresponding timing point for $n = 1$ if it is applied as $\pi(\text{C}, x)$. For the discussion presented here, a $\pi(\text{C}, y)$ pulse will be assumed, yielding, after the last $1/2J$ time period,

$$-S_x^{\text{C}}(S_z^{\text{H}})^2\sin\theta\cos\theta \rightarrow \frac{1}{2}S_x^{\text{C}}(U^{\text{H}})^2\sin 2\theta \quad (21)$$

Consequently, a 1:2:1 doublet is observed that is nulled when $\theta = \frac{1}{2}\pi$, maximized when $\theta = \frac{1}{4}\pi$, and maximized but inverted in phase when $\theta = \frac{3}{4}\pi$. Clearly, the effects of θ are the same as for $\pi J\Delta$ in the INEPT sequence; indeed, for the general case, the signal intensity is modulated as $\sin\theta\cos^{n-1}\theta$, since it arises from the spin coherence

$$S_x^{\text{C}}(U^{\text{H}})^n\sin\theta\cos^{n-1}\theta \quad (22)$$

Figure 2 and Figure 3 illustrate the enhancements possible when the DEPT pulse sequence is employed to record ^{29}Si and ^{15}N NMR spectra. These results are consistent with the values given in Table 3, on substituting θ for $\pi J\Delta$.

The DEPT pulse sequence can be utilized to produce edited ^{13}C spectra,¹⁰ that is, to obtain proton-decoupled ^{13}C spectra arising only from CH groups, CH_2 groups, or CH_3 groups. To edit a ^{13}C spectrum, spectra are obtained using the DEPT method for three different values of θ : $\theta_1 = \frac{1}{4}\pi$, $\theta_2 = \frac{1}{2}\pi$, and $\theta_3 = \frac{3}{4}\pi$. In order to have comparable intensities, twice as many acquisitions are taken for θ_2 as for the other θ values. For perfectly homogeneous rf pulses, the θ_2 spectrum is the CH subspectrum. The other subspectra are obtained by linear combinations of the acquired spectra:

$$\left. \begin{aligned}
 \text{CH}_2 \text{ subspectrum} &\rightarrow (\theta_1 - \theta_3) \text{ combination} \\
 \text{CH}_3 \text{ subspectrum} &\rightarrow (\theta_1 + \theta_3 - 0.707\theta_2) \text{ combination}
 \end{aligned} \right\} \quad (23)$$

An example illustrating these ideas is shown in Figure 4.

Variations on the INEPT and DEPT pulse sequence have been published, but the basic ideas are the same.¹¹ The only significant variation is the POMMIE pulse train,¹² which for $^1\text{H} \rightarrow ^{13}\text{C}$ polarization transfer is

$$\begin{aligned}
 &\frac{\pi}{2}(\text{H}, x) - \frac{1}{2J} - \frac{\pi}{2}(\text{C}, x)\pi(\text{H}) - \frac{1}{2J} - \frac{\pi}{2}(\text{H}, x) \\
 &\times \frac{\pi}{2}(\text{H}, \Psi)\pi(\text{C}) - \frac{1}{2J} - \text{Acquire } ^{13}\text{C}
 \end{aligned} \quad (24)$$

$\frac{1}{2}\pi(\text{H}, \Psi)$ is a $\frac{1}{2}\pi$ pulse applied phase-shifted by an amount Ψ from the x axis of the rotating frame. The interested reader can, using the equations presented in Table 1, show that the observed coherence arises from

$$S_x^{\text{C}}(U^{\text{H}})^n\sin\Psi\cos^{n-1}\Psi \quad (25)$$

for the spin grouping CH_n . Comparing the results given in equations (12), (22), and (25), the correspondence between Δ , θ , and Ψ can be seen.

Figure 2 79.5 MHz ^{29}Si spectra of a silicone oil (50% in C_6D_6). The ^1H -coupled spectrum (lower) was acquired using a spectral width of 4 kHz (32 acquisitions) and without NOE. The DEPT spectrum was recorded with $\theta = 0.13\pi$. The multiplet plotted to the right corresponds to the $\text{Si}(\text{CH}_3)_2$ groups of the polymer chain. The multiplet to the left [30 ppm to high frequency (downfield)] is from $\text{Si}(\text{CH}_3)_3$ end groups. The two-bond scalar coupling used to induce the transfer was taken as 7.4 Hz. A recycle time of 7 s was used

Figure 3 40.5 MHz ^{15}N spectrum of formamide (90% in $\text{DMSO}-d_6$, 10 mm sample). The ^1H -coupled spectrum (one acquisition) is compared with the DEPT spectrum acquired with $\theta = \frac{1}{4}\pi$

3.4 Inverse Polarization Transfer

It has been assumed above that $|\gamma_S| > |\gamma_I|$ and it has been illustrated how polarization transfer from more abundant large- γ spins, ^1H , to heteronuclei is advantageous for recording

heteronuclear NMR. The situation can arise where the ^1H -detect $I \rightarrow ^1\text{H}$ polarization transfer (called 'inverse,' since superficially an S/N reduction by an amount γ_I/γ_H must occur) experiment¹³ may be useful. This situation arises when ^1H spectroscopy is to be carried out in H_2O as solvent and mainly

Figure 4 Edited ^{13}C spectra of ristocetin A in DMSO (120 mg mL^{-1} , 70°C) at 100.6 MHz . The bottom spectrum is the normal ^1H -decoupled spectrum (400 acquisitions), showing all ^{13}C resonances. The edited spectra were acquired as per the text, and result from the combination of 800 acquisitions with $\theta = \frac{1}{4}\pi$ and $\frac{3}{4}\pi$, and 1600 acquisitions at $\theta = \frac{1}{2}\pi$

if metabolic processes are to be followed using ^{13}C -labeled precursors. In this discussion, one pulse sequence is analyzed. This is the $^{13}\text{C} \rightarrow ^1\text{H}$ inverse DEPT sequence^{14,15}

$$\begin{aligned} \text{randomize: } & \frac{\pi}{2}(\text{C}, \pm x) - \frac{1}{2J} - \pi(\text{C})\theta(\text{H}, x) - \frac{1}{2J} \\ & - \frac{\pi}{2}(\text{C}, y)\pi(\text{H}, y) - \frac{1}{2J} - \text{Acquire } ^{13}\text{C} \end{aligned} \quad (26)$$

A purging pulse, $\theta(\text{H}, x)$, can be added before data acquisition.¹⁵ Its benefits are illustrated in Figure 5. The following points should be noted.

1. The pulse sequence begins by randomizing the ^1H spins. An rf burst at the ^1H resonance frequency to cover the ^1H spectral width is applied. The inhomogeneity of the ^1H rf coil ensures that there is no net ^1H magnetization remaining. However, because of the $^1\text{H} \rightarrow ^{13}\text{C}$ NOE, the ^{13}C magnetization is boosted by a factor of approximately 3. (Note that ^1H decoupling per se does not necessarily yield zero net ^1H magnetization at the instant the decoupling field is removed—a randomization is required.) The physics of the first step of this pulse sequence is thus complex. Because of the NOE, the observed ^1H signal induced by the transfer process will only be reduced by one-quarter compared with the natural ^1H magnetization.
2. If the randomization field is completely efficient then, prior to the application of any rf pulse, $\langle S \rangle = 0$ from all sources of ^1H signal, including that from H_2O . ^1H magnetization from H_2O as solvent builds up during the pulse sequence, and, given that H_2O is 55 M in concentration, a significant ^1H signal can still be observed. However, its phase does

not depend upon the phase of the first $\frac{1}{2}\pi(\text{C})$ pulse. Thus, further H_2O suppression will result, with phase alternation of this pulse and concurrent phase alternation of the receiver.

The product operator analysis of this pulse sequence is presented for a CH_2 group. The initial coherence is $S_z^{\text{C}}(U^{\text{H}})^2$, and the following changes occur:

$$\begin{aligned} S_z^{\text{C}}(U^{\text{H}})^2 & \xrightarrow{\frac{1}{2}\pi(\text{C}, x)} S_y^{\text{C}}(U^{\text{H}})^2 \xrightarrow{1/2J} -S_y^{\text{C}}(S_z^{\text{H}})^2 \\ & \xrightarrow{\theta(\text{H}, x)} -S_y^{\text{C}}S_z^{\text{H}}S_y^{\text{H}} \sin \theta \cos \theta \end{aligned} \quad (27)$$

Following the $\theta(\text{H}, x)$ pulse there are four terms, only one of which can yield a detectable ^1H signal. This term arises from $S_y^{\text{C}}S_z^{\text{H}}S_y^{\text{H}}$, and has an angular dependence of $\sin 2\theta$. It is thus maximized at $\theta = \frac{1}{4}\pi$, zero at $\theta = \frac{1}{2}\pi$, and maximized but phase-inverted at $\theta = \frac{3}{4}\pi$. During the remaining period of the pulse sequence, the following changes occur to yield a detectable signal:

$$S_y^{\text{C}}S_z^{\text{H}}S_y^{\text{H}} \xrightarrow{1/2J} -S_x^{\text{C}}U^{\text{H}}S_y^{\text{H}} \xrightarrow{\frac{1}{2}\pi(\text{C}, y)} -S_z^{\text{C}}U^{\text{H}}S_y^{\text{H}} \xrightarrow{1/2J} U^{\text{C}}U^{\text{H}}S_x^{\text{H}} \quad (28)$$

Any detectable H_2O signal will be phase shifted by $\frac{1}{2}\pi$ relative to $U^{\text{C}}U^{\text{H}}S_x^{\text{H}}$, and can be further removed from the detection plane by application of a $\theta(\text{H}, x)$ purging pulse. Results using this pulse sequence to monitor metabolism of ^{13}C -labeled glucose in a mouse liver cell extract (H_2O solvent) are shown in Figure 6. Suppression of the H_2O signal by a factor of 8×10^5 is possible using reverse polarization transfer.¹⁵ The important point to note is that most of the signal suppression is

Figure 5 Application of the reverse DEPT pulse sequence to a sample of ^{13}C -labeled ethanol in neat H_2O . (a) Normal pulse-and-collect low-gain ^1H spectrum. (b) High-gain pulse-and-collect spectrum showing the ethanol CH_2 protons. (c) Reverse DEPT spectrum without the purging pulse. (d) Reverse DEPT spectrum with the purging pulse. In all cases, the sample concentration was 100 mM. (e) Reverse DEPT spectrum, sample concentration 10 mM

Figure 6 Application of the reverse DEPT pulse sequence to monitor metabolism of ^{13}C -labeled glucose by a mouse liver cell extract. (a) Normal pulse-and-collect spectrum in H_2O . (b) Reverse DEPT spectrum showing the α and β anomeric proton resonances. (c) After 1.5 h of metabolism, two different CH_2 proton resonances are observed: A and B. (d) An edited spectrum as per Brooks et al.,¹⁵ confirming that the metabolic product arises from a CH_2 molecular fragment

achieved prior to the detection step, and thus the full dynamic range of the receiver can be utilized to detect weak signals.

3.5 2D Experiments

A variety of multidimensional NMR experiments are possible based upon either a modified INEPT or DEPT pulse

Figure 7 Edited 2D ^{13}C -observe ^{13}C - ^1H heteronuclear cross correlation spectra obtained from a saturated solution of menthol in CDCl_3 . Four acquisitions per t_1 increment and 512 points in the ω_1 direction were acquired. Values of θ were $\theta = \frac{1}{4}\pi$ and $\theta = \frac{1}{2}\pi$ (the CH subspectrum)

sequence or on using these pulse sequences as sources of transverse magnetization¹⁶ (for a discussion of the possible 2D pulse sequences, see Kessler³). A simple example is provided by the heteronuclear chemical shift correlation experiment

$$\begin{aligned} & \frac{\pi}{2}(\text{H}, x) - \frac{t_1}{2} - \pi(\text{C}) - \frac{t_1}{2} - \frac{1}{2J} - \pi(\text{H}) \frac{\pi}{2}(\text{C}) \\ & - \frac{1}{2J} - \theta(\text{H}, y)\pi(\text{C}) - \frac{1}{2J} - \text{Acquire } ^{13}\text{C} \end{aligned} \quad (29)$$

During the time t_1 , ^1H chemical shift evolution occurs; ^{13}C decoupling in the ω_1 direction is achieved by insertion of the $\pi(\text{C})$ pulse. By setting θ as noted above, it is possible to generate 2D heteronuclear chemical shift correlated subspectra. The results of such an experiment are shown in Figure 7.

4 CONCLUSIONS

As noted by Ernst,² polarization transfer experiments are a subclass of the general class of coherence transfer processes. Previously, the term 'population transfer' had also been used to signify the fact that the Zeeman population of the coupled spin partner was controlling the observed S/N. This article has focussed on the methodology and utility of polarization-transfer experiments, and has attempted to explain the spin physics involved without recourse to more complex quantum mechanical descriptions. (Hartmann-Hahn cross polarization¹⁷ via scalar coupling has been neglected

because of limitations of space; for details, see Doddrell et al.¹⁸) As has been illustrated here, these experiments have wide applicability for structural studies using magnetic resonance.

1 INTRODUCTION

In the late 1970s and early 1980s the basic principles of two-dimensional NMR were beginning to become clear. It was also clear that the experiments being used at that time would not be sufficient to solve many interesting problems, especially those concerning nucleic acids and proteins. The experiments that were then in use included INEPT, INADEQUATE, NOESY, homonuclear and heteronuclear J spectroscopy, as well as variants of what has come to be known as COSY type experiments and heteronuclear correlation experiments which involved detection of the heteronucleus.

The author's interest in two-dimensional NMR began with the use of heteronuclear ^{31}P - ^1H experiments to utilize the ^{31}P nucleus to 'spy' on the proton nuclei.¹ These experiments were originally aimed at obtaining proton-proton and proton-phosphorus scalar couplings and proton chemical shifts via use of experiments such as the one schematically illustrated in Figure 1. In this basic type of heteronuclear two-dimensional NMR experiment the free precession information of the protons is transferred to the heteronuclear 'spy' nucleus, in this case ^{31}P , by the simultaneous proton and heteronuclear pulses.

The proton spectrum which is detected in this type of experiment can be thought of as a difference spectrum.¹ The normal proton spectrum can be thought of as arising from the sum of the two subspectra which arise from the two possible polarizations of the heteronucleus. The proton spectrum detected in the heteronuclear experiment is the difference between these two subspectra. This principle is illustrated in Figure 2. The spectrum in (a) is the sum of the two subspectra corresponding to the two polarizations of the phosphorus nucleus and is the normal one-dimensional proton spectrum. The spectra in (b) and (c) are the two proton subspectra corresponding to the two different polarizations of the phosphorus nucleus. The spectrum in (d) is the difference spectrum between the two subspectra.

The comparison of the predicted and observed results is shown in the spectra on the right-hand side of Figure 2 along with the structure of 2'-guanosine monophosphate (2'-GMP) which was the molecule used for these experiments. There is good agreement between the predicted and observed spectra.

This single quantum experiment and various multiple quantum variations were applied to a number of nucleotides

including ones which exhibit strong proton-proton scalar coupling and scalar coupling between the protons and more than one phosphate.²⁻⁵ In addition, the flip angle dependence of the intensities of the individual lines in the heteronuclear spectra was extensively investigated.^{3,4,6} These studies allowed us to analyze essentially any spectrum obtained in a heteronuclear two-dimensional chemical shift correlation experiment. These methods were even applied to nucleotides bound to an enzyme.⁷

In these heteronuclear two-dimensional experiments, the heteronucleus could report on the protons which had scalar couplings to the heteronucleus but did not report directly on any other protons. For example, in both the predicted and experimental results on 2'-GMP, no information about the chemical shift of the H-3' proton is obtained. Thus, the results of a heteronuclear experiment on 2'-GMP do not offer complete information about the protons which are not directly coupled to the heteronucleus. As in many cases, the information which is of most interest is not necessarily the most accessible information. The nomenclature which was introduced was to call the protons directly coupled to the heteronuclear 'spy' as 'neighbor' nuclei and the protons coupled to the neighbors as 'remote' nuclei.

One way to obtain information about the remote nuclei was to apply a weak continuous wave decoupling field at the chemical shift of the remote nucleus during the evolution time.⁸ When the decoupling field was on resonance then the coupling of the remote nucleus with the neighbor nucleus would be suppressed. Figure 3 illustrates the expected change in a heteronuclear two-dimensional experiment. At the time that this double resonance, two-dimensional experiment was first conceived it was not trivial to carry it out. The Varian XL-200 spectrometer that was in use at the time required *milliseconds* to carry out a change in the power level of the proton channel, since the power change was carried out by means of *mechanical* relays which could be monitored by simply listening to the spectrometer. However, application of a proton decoupling field during the evolution time of a heteronuclear two-dimensional experiment could be implemented and typical results are shown in Figure 4. As expected the double resonance, two-dimensional experiment did allow the determination of the couplings between the neighbor and remote protons. The chemical shift of the remote protons could be determined by observing the neighbor protons as a function of the frequency of the decoupling field and this was actually carried out on a nucleotide-protein complex.⁷

2 THE ORIGINAL RELAY TRANSFER EXPERIMENTS

About the time that the galley proofs on the above work were being corrected it became apparent that this was not a very clever way to obtain information about the remote protons. The basic heteronuclear two-dimensional experiment can be considered as the successor of the process of obtaining a series of one-dimensional spectra of the heteronucleus as a function of the frequency of a proton decoupling field. A better way to obtain information about the remote protons is to substitute a frequency independent procedure for the decoupling field applied during the evolution time.

2 RELAYED COHERENCE TRANSFER EXPERIMENTS

Figure 1 (a) A depiction of the basic pulse sequence used for heteronuclear chemical shift correlation spectroscopy. (b) The energy levels of a two-spin heteronuclear spin system and (c) the proton and phosphorus spectra together with labelings of the subspectra. (Adapted from Bolton and Bodenhausen¹)

This substitution could be based on the same basic idea as the heteronuclear two-dimensional NMR experiment, that is, the transfer of magnetization between nuclei which are scalar coupled by means of pulses rather than a set of experiments varying the frequency of the decoupling field. The basic procedure was to have two, successive magnetization transfers. The first magnetization transfer would be from remote to neighbor protons and the second transfer from the neighbor protons to the heteronuclear spy nucleus whose free precession would be detected.

Thus, the basic idea was simple and so obvious it was surprising no one had implemented it much earlier. The experiment was a straightforward combination of two two-dimensional experiments: a proton–proton COSY experiment and a heteronuclear two-dimensional chemical shift correlation experiment. The pulse sequence for a proton–proton COSY experiment is $90^\circ, t_1, 90^\circ, t_2$. The pulse sequence for a heteronuclear two-dimensional experiment is that shown in Figure 1. The pulse sequence for the combined heteronuclear experiment is

$$\begin{aligned} {}^1\text{H}: & 90^\circ, t_1, 90^\circ, t_m, 90^\circ \\ \text{X}: & 90^\circ, t_2 \end{aligned}$$

The mixing time, t_m , is chosen to be long enough for the protons to become antiphase with respect to both the heteronuclear and homonuclear couplings. A typical value for a proton–phosphorus experiment is 30 ms. This experiment was named the *relayed coherence transfer* experiment as the

magnetization is relayed from the remote to the neighbor to the spy.^{9,10}

The first experiments were carried out on phosphothreonine⁹ with typical data shown in Figure 5. The experiment succeeded in correlating both the remote and neighbor protons with the heteronuclear spy, which in this case includes all of the nonexchangeable protons of the molecule. This demonstrated that two two-dimensional experiments could be combined into a single experiment. In addition, the relay transfer experiment contains essentially all of the information present in the separate two-dimensional experiments.

While the application of the heteronuclear relay transfer experiment to molecules containing phosphorus was a success, the much more interesting application was to use ^{13}C as the spy nucleus.¹⁰ The original pulse sequence is

with t_H the delay time to allow the magnetization to become antiphase with respect to the heteronuclear couplings so that transfer can occur, and t_C the delay time to allow the carbon

Figure 2 The left side of the figure contains the normal proton spectrum of 2'-GMP (a); the two subspectra which arise from the two polarizations of the phosphorus heteronucleus (b,c); and the predicted heteronuclear spectrum of this sample (d). The right side contains a comparison between the predicted heteronuclear spectrum (top) and the observed spectrum (bottom). (Adapted from Bolton and Bodenhausen¹)

Figure 3 The predicted changes in the heteronuclear two-dimensional spectrum of cytosine 2'-monophosphate upon decoupling of the H-1' proton are shown. The decoupling removes the H-1'–H-2' coupling from the heteronuclear spectrum. (Adapted from Bodenhausen and Bolton⁶)

Figure 4 The spectrum on the top left is the experimental heteronuclear chemical shift correlation spectrum of 2'-CMP and on the bottom left the predicted spectrum. The spectrum on the top right is the experimental heteronuclear chemical shift correlation spectrum of 2'-CMP obtained with decoupling of the H-1' proton and on the bottom right the predicted spectrum. (Adapted from Bodenhausen and Bolton⁶)

Figure 5 The two-dimensional spectrum is a relay transfer data set obtained on a sample of phosphothreonine. Along the vertical axis is the ^{31}P frequency and along the horizontal the proton frequencies. The heteronuclear coupling is present in each dimension. The trace shown at the top is in the phase sensitive mode. (Adapted from Bolton and Bodenhausen⁹)

magnetization to become in-phase to allow acquisition of the data with proton decoupling.

Consider the case of 1-pentanol, which is $\text{C}_{(5)}\text{H}_3\text{-C}_{(4)}\text{H}_2\text{-C}_{(3)}\text{H}_2\text{-C}_{(2)}\text{H}_2\text{-C}_{(1)}\text{H}_2\text{-OH}$. Carbon-5 will correlate with its neighbor protons as well the remote protons attached to carbon-4. Carbon-4 will correlate with the remote protons

Figure 6 A two-dimensional spectrum relay transfer data set obtained on 1-pentanol. (Adapted from Eich et al.¹¹)

of carbon-5 and carbon-3 as well as its own neighbor protons. Thus, a single relay experiment on a molecule like pentanol can allow complete sequential assignment of both the proton and ^{13}C spectra, since each carbon will correlate not only with its neighbor protons but the remote protons on adjacent carbons. Thus, the relay data can allow the sequential assignments of the carbon and proton resonances.¹⁰ The spectrum in Figure 6 shows that the relay transfer information does indeed allow the sequential connectivities to be made. The only additional information which is needed is to be able to assign cross peaks to the neighbor and remote categories. This can be done either by comparison with a heteronuclear two-dimensional experiment or by elimination of the neighbor signals.

Almost simultaneously with the introduction of the heteronuclear relay transfer experiments, Eich, Bodenhausen and Ernst demonstrated homonuclear relay transfer experiments.¹¹ These experiments were based on the same principles as the heteronuclear relay transfer experiments.

The original versions of the relay transfer experiments were modified to include improved phase cycling and methods to discriminate between neighbor and remote protons; multiple quantum versions were introduced as were constant time variations. These procedures allowed a number of systems to be investigated. The product operator description of relay transfer experiments can be found elsewhere.^{9,12} The main impact of relay transfer experiments was the demonstration that two, or more, two-dimensional experiments could be combined to yield a new experiment more powerful than any combination of the results of the individual experiments.

3 THE DEVELOPMENT OF RELAY TRANSFER EXPERIMENTS

Subsequent to the original introduction of heteronuclear relay transfer experiments there have been three types of significant improvements in the experimental approach. The original experiments relied on free precession of the protons during the mixing time to obtain magnetization which contained at least some antiphase character with respect to both the proton

and heteronucleus.^{9,10,13} More uniform proton–proton transfer can be obtained by the use of a homonuclear spin lock during the magnetization transfer followed by an INEPT, or analogous, heteronuclear transfer.^{14,15} This procedure allows heteronuclear relay transfer experiments to be successfully carried out on a wide range of spin systems. The use of homonuclear spin locks is discussed elsewhere in this Encyclopedia.

A major improvement in the sensitivity of the heteronuclear relay transfer experiment was the conversion to proton detection.¹⁶ In the proton detection heteronuclear relay transfer experiments, the proton magnetization is transferred to the heteronucleus which is then allowed to precess. The magnetization is then transferred back to the neighbor protons. The magnetization can then be transferred to the remote protons and, with a spin lock throughout the proton spin system, the magnetizations of both the remote and neighbor protons detected. The original proton detection relay transfer experiments were carried out without the use of spin locks¹⁶ and the first application to a labeled protein occurred in 1986.¹⁷ The proton detection versions of heteronuclear relay transfer currently in use are heteronuclear single quantum spectroscopy (HSQC)–TOCSY, heteronuclear multiple quantum spectroscopy (HMQC)–NOESY, and so on.^{18–21} Proton–phosphorus relay correlations are now being performed via three-dimensional experiments which transfer magnetization via spin locks from phosphorus to neighbor protons to remote protons on DNA at millimolar concentrations.²²

The conversion of heteronuclear relay transfer experiments into three-dimensional experiments is accomplished by the use of an evolution time rather than a constant mixing time. This allows experiments to be performed in which the neighbor-remote proton connectivities are in two-dimensional planes resolved by the frequencies of the spy nucleus along the third frequency axis. Three-dimensional HSQC–TOCSY experiments, for example, can be thought of as the combination of two, two-dimensional experiments into a three-dimensional experiment. Extensions to four- and five-dimensional experiments have also been made. The availability of isotopically labeled biological materials has made the development and application of these types of experiments powerful tools for studying the structure and dynamics of proteins and nucleic acids.

The original version of the heteronuclear relay transfer experiment has been vastly superseded by its offspring, both in terms of sensitivity and resolution. Improvements in the sensitivity and resolution of the two-dimensional heteronuclear relay experiment continue to be developed.²³ The fundamental idea of the relay transfer experiments, which is to combine two or more magnetization transfers to obtain a new experiment which contains more information than is present in the results of both of the parent experiments, has remained a very fruitful idea.

1 INTRODUCTION

Of the numerous methods that have been devised for manipulating magnetization, the cross-polarization method invented by Hartmann and Hahn (see also *Cross Polarization in Solids*) may be regarded as one of the most ingenious.¹ It is also one of the most difficult experiments to explain in simple pedagogical terms, since semiclassical vector pictures do not appear to provide adequate insight. Historically, cross polarization was first developed for use in solids, more specifically to bring about a transfer of magnetization between unlike spins such as protons and ¹³C, henceforth referred to as species *I* and *S*. Early experiments were not so much concerned with the idea of detecting the enhanced *S* magnetization, but rather with monitoring the loss of *I* magnetization that occurs during polarization transfer. Cross polarization gained a great deal of popularity when the emphasis was shifted to the detection of enhanced *S* nuclei,² particularly in combination with magic angle spinning.

In solids, a Hartmann–Hahn transfer by cross polarization can be described in terms of spin thermodynamics, using suitably defined heat reservoirs, with heat capacities and kinetic rates to describe the flow of order from one bath to another. This type of description is not applicable to magnetic resonance in liquids, for it presupposes large ensembles of coupled spin systems which only occur in solids with extensive dipolar interactions. Besides, the thermodynamic description remained for many years unfamiliar to most specialists of liquid state NMR, so that cross polarization tended to be confined to solid state applications. It was perhaps fortunate that the thermodynamic description was not completely satisfactory to describe the behavior in solids, particularly for materials that contain reasonably isolated spin pairs *I* and *S*, such as ferrocene. Indeed, among other things, the thermodynamic description failed to account for the appearance of so-called transient oscillations in cross polarization.³ These phenomena could however be understood by adapting to the solid state the density-operator approach which is commonly used for the description of scalar-coupled spin systems in liquids.³

Once it had become clear that cross polarization could be described as a coherent effect, and that the relevant (heteronuclear) coupling Hamiltonian which drives the phenomenon has the same form $\hat{I}_z\hat{S}_z$ in dipole-coupled solids as in scalar-coupled liquids, the main obstacle to cross fertilization from solids to liquids was removed. This led to detailed studies^{4,5} of heteronuclear Hartmann–Hahn effects in liquids, using simultaneous nonselective spin locking of both species *I* and *S*. That Hartmann–Hahn effects could also occur between *like* spins (e.g. between two protons I^A and I^X) was, in a sense, tacitly assumed in the early thermodynamic description, but this feature could not be exploited for any useful purpose until the advent of two-dimensional Fourier transform spectroscopy. The use of homonuclear Hartmann–Hahn effects in nonselective two-dimensional correlation spectroscopy led to Total Correlation Spectroscopy (TOCSY), which is today one of the most popular tools in the arsenal of multidimensional NMR.⁶ It derives its name from the fact that the magnetization is transferred between all spins belonging to a common network of scalar-coupled spins. This method is sometimes referred to as ‘Homonuclear Hartmann–Hahn’ (HOHAHA) spectroscopy. The choice of nomenclature merely reflects a preference for one or the other of the schools of thought that have given birth to these abbreviations.

In this article, we focus attention on Hartmann–Hahn effects that arise under doubly-selective irradiation. Such effects cannot give rise to ‘total’ coherence transfer processes as encountered in TOCSY, hence the expression ‘doubly-selective homonuclear Hartmann–Hahn’ (DS-HOHAHA) for this type of experiment.

2 HAMILTONIAN AND COHERENCE TRANSFER

Consider for simplicity two weakly scalar-coupled spins I^A and I^X with $I = \frac{1}{2}$, such as two protons, which are subjected to two selective radiofrequency (rf) fields that are applied precisely on-resonance at the two chemical shifts ν_A and ν_X . We assume that the rf amplitudes ν_{1A} and ν_{1X} of these two rf fields are precisely equal. This can be easily achieved in practice by setting the rf carrier frequency half-way between the two chemical shifts, $\nu_c = (\nu_A + \nu_X)/2$, and by modulating the shape of the rf pulse with a cosine-wave, i.e. by multiplying the envelope with $\cos \nu_a t$, where $\nu_a = (\nu_A - \nu_X)/2$, so that the rf spectrum splits into two sidebands which coincide with the two chemical shifts ν_A and ν_X . Each sideband has an amplitude $\nu_1 = \nu_{1A} = \nu_{1X}$. In the usual laboratory frame, the Hamiltonian is:

$$\begin{aligned}\hat{\mathcal{H}} = & 2\pi\nu_A\hat{I}_z^A + 2\pi\nu_X\hat{I}_z^X \\ & + 4\pi\nu_1\cos 2\pi\nu_a t[(\hat{I}_x^A + \hat{I}_x^X)\cos 2\pi\nu_c t \\ & + (\hat{I}_y^A + \hat{I}_y^X)\sin 2\pi\nu_c t] + \pi J_{AX}2\hat{I}_z^A\hat{I}_z^X\end{aligned}\quad (1)$$

This Hamiltonian can be simplified⁷ by transformation into a frame rotating at the average precession frequency $\nu_c = (\nu_A + \nu_X)/2$, which leads to:

$$\begin{aligned}\hat{\mathcal{H}} = & 2\pi\nu_a\hat{I}_z^A - 2\pi\nu_a\hat{I}_z^X + 4\pi\nu_1\cos 2\pi\nu_a t(\hat{I}_x^A + \hat{I}_x^X) \\ & + \pi J_{AX}2\hat{I}_z^A\hat{I}_z^X\end{aligned}\quad (2)$$

2 SELECTIVE HARTMANN-HAHN TRANSFER IN LIQUIDS

A second transformation⁷ into a doubly-rotating frame, also called interaction frame, leads to the removal of the first two terms, which correspond to Zeeman interactions. If we neglect time-dependent nonsecular terms, which describe the weak interaction of the rf field component rotating at ν_A with spin I^X and of the rf component at ν_X with spin I^A , one obtains the simple form:

$$\hat{\mathcal{H}} = 2\pi\nu_1(\hat{I}_x^A + \hat{I}_x^X) + \pi J_{AX}2\hat{I}_z^A\hat{I}_z^X \quad (3)$$

The effect of this Hamiltonian on an arbitrary initial condition can be calculated analytically.⁷ If we assume for simplicity that the initial density operator σ has the following form at the beginning of the Doubly-Selective Irradiation (DSI) interval τ_{DSI} :

$$\sigma(\tau_{\text{DSI}} = 0) = \hat{I}_x^A \quad (4)$$

it can be shown that this in-phase coherence is transformed into a superposition of six terms:

$$\langle \hat{I}_x^A \rangle(\tau_{\text{DSI}}) = (1/2)[\cos \omega_J \tau_{\text{DSI}} + (\omega_J/\omega_{\text{eff}})^2 \cos \omega_{\text{eff}} \tau_{\text{DSI}} + (2\omega_1/\omega_{\text{eff}})^2] \quad (5)$$

$$\langle \hat{I}_x^X \rangle(\tau_{\text{DSI}}) = (1/2)[- \cos \omega_J \tau_{\text{DSI}} + (\omega_J/\omega_{\text{eff}})^2 \cos \omega_{\text{eff}} \tau_{\text{DSI}} + (2\omega_1/\omega_{\text{eff}})^2] \quad (6)$$

$$\langle 2\hat{I}_y^A\hat{I}_z^X \rangle(\tau_{\text{DSI}}) = (1/2)[\sin \omega_J \tau_{\text{DSI}} + (\omega_J/\omega_{\text{eff}}) \sin \omega_{\text{eff}} \tau_{\text{DSI}}] \quad (7)$$

$$\langle 2\hat{I}_z^A\hat{I}_y^X \rangle(\tau_{\text{DSI}}) = (1/2)[- \sin \omega_J \tau_{\text{DSI}} + (\omega_J/\omega_{\text{eff}}) \sin \omega_{\text{eff}} \tau_{\text{DSI}}] \quad (8)$$

$$\langle 2\hat{I}_z^A\hat{I}_z^X \rangle(\tau_{\text{DSI}}) = (\omega_1\omega_J/\omega_{\text{eff}}^2)(1 - \cos \omega_{\text{eff}} \tau_{\text{DSI}}) \quad (9)$$

$$\langle 2\hat{I}_y^A\hat{I}_y^X \rangle(\tau_{\text{DSI}}) = -(\omega_1\omega_J/\omega_{\text{eff}}^2)(1 - \cos \omega_{\text{eff}} \tau_{\text{DSI}}) \quad (10)$$

where $\omega_J = \pi J$ and $\omega_{\text{eff}} = (4\omega_1^2 + \pi^2 J^2)^{1/2}$. The remaining 10 terms that could arise in the 16-dimensional density operator of an isolated two-spin system remain equal to zero. The expectation values of equations (5)–(10) are shown graphically in Figure 1 as a function of the doubly-selective irradiation period τ_{DSI} . It should be noted that for $\tau_{\text{DSI}} = 1/J_{AX}$, the in-phase term $\hat{I}_x^A$ is *completely* converted into in-phase magnetization $\hat{I}_x^X$. However, if τ_{DSI} is not precisely ‘matched’ to the inverse of the coupling constant (either because the latter is not known, or because relaxation makes it desirable to keep the transfer period as short as possible), one cannot avoid the appearance of antiphase terms $\langle 2\hat{I}_y^A\hat{I}_z^X \rangle$ and $\langle 2\hat{I}_z^A\hat{I}_y^X \rangle$,

Figure 1 Expectation values of the six nonvanishing components of the density operator of a scalar-coupled two-spin system in the course of doubly-selective Hartmann–Hahn transfer, starting with in-phase magnetization of spin I^A as described by equations (5)–(10). (Reproduced by permission of North-Holland Elsevier Science Publishers from Zwahlen et al.⁷)

of longitudinal two-spin order $\langle 2\hat{I}_z^A \hat{I}_z^X \rangle$, and of the two-spin term $\langle 2\hat{I}_y^A \hat{I}_y^X \rangle$, which corresponds to a superposition of zero- and double-quantum coherences. In some experiments, it is necessary to eliminate these undesirable terms by some combination of selective pulses, phase cycling, or gradient suppression schemes.

3 DECOUPLING AND RELAXATION EFFECTS

It is a remarkable feature of selective Hartmann-Hahn transfer in liquids that the two nuclei I^A and I^X that are irradiated selectively are in effect *decoupled* from all other spins in their environment. This can be rationalized by noting that the two selected spins are both spin locked and hence quantized in the transverse plane, while all other spins (whether of the same species, e.g. protons, or of other, 'heteronuclear' species, such as ^{13}C) are not perturbed and hence remain quantized along the longitudinal axis. This implies that the transfer of coherence is *highly directional*, i.e. that the coherence cannot propagate to any other spins in the coupling network, except if they are degenerate in chemical

shift and hence also affected by one of the selective spin locking fields. This 'directional' feature may be appreciated in Figure 2, which illustrates a transfer of in-phase magnetization in a high-resolution proton spectrum of a peptide. This stands in contrast to nonselective Hartmann-Hahn transfer as it occurs in TOCSY,⁶ where the coherence is 'spread out' among all coupling partners, so that the signal intensities depend on the magnitudes of all scalar coupling constants in the network.

On the other hand, the efficiency of the doubly-selective Hartmann-Hahn transfer is limited by relaxation. The Hamiltonian of equation (3) contains only one bilinear term $\pi J_{AX} 2\hat{I}_z^A \hat{I}_z^X$ (as opposed to two terms $\pi J_{AX} 2\hat{I}_z^A \hat{I}_z^X + \pi J_{AX} 2\hat{I}_y^A \hat{I}_y^X$ that arise in TOCSY), so that the transfer from I^A to I^X is optimum for $\tau_{\text{DSI}}^{\text{opt}} = (J_{AX})^{-1}$. This stands in contrast to $\tau_{\text{DSI}}^{\text{opt}} = (2J_{AX})^{-1}$ for TOCSY and other nonselective Hartmann-Hahn experiments. Thus the signal intensity that can be obtained with the directional doubly-selective Hartmann-Hahn method may suffer from relaxation, particularly in macromolecules. It should be noted that the relevant relaxation time is $T_{1\rho}$ rather than T_2 , and that, for a variety of reasons,⁸ $T_{1\rho}$ can be longer than T_2 and hence more favorable.

It is also possible to achieve homonuclear Hartmann-Hahn effects with modified Hamiltonians so that the trajectories in Liouville space depend in a different manner on longitudinal and transverse relaxation. This applies to TAIlored Correlation SpectroscopY (TACS_Y),⁹ and to broadband FLOPSY methods¹⁰ used in combination with DANTE-like intervals,¹¹ all of which have more favorable profiles (transfer efficiency as a function of offset) than straight doubly-selective irradiation.

4 ONE-DIMENSIONAL APPLICATIONS

The example of Figure 2 shows how a selective transfer makes it possible to separate multiplets which suffer from extensive overlap in normal one-dimensional spectra.¹² To record such multiplets, some previous knowledge about the chemical shifts is of course required. The shifts of a coupled pair of spins are normally estimated from a low-resolution two-dimensional correlation spectrum (COSY), but the scalar coupling need not be known, since the duration of the doubly-selective irradiation interval τ_{DSI} can be calibrated empirically to optimize the transfer. The digital resolution of a multiplet such as that shown in Figure 2 is normally much better than that of a multiplet extracted from a two-dimensional spectrum. The doubly-selective Hartmann-Hahn method should therefore be regarded as a complement to (rather than a competitor of) two-dimensional correlation techniques.

Figure 3 shows another application of the selective Hartmann-Hahn effect: the measurement of relaxation parameters of nuclei with overlapping resonances.^{8,13} This principle can easily be extended to encompass the determination of longitudinal relaxation rates (T_1) by selective or nonselective inversion-recovery, the measurement of $T_{1\rho}$ by selective spin locking, and of T_2 by selective refocusing.¹⁴ It is also possible to measure cross relaxation rates in a selective manner (see *Selective NOESY*). In most cases, the methods used for probing relaxation phenomena are not innovative by themselves, and the Hartmann-Hahn transfer is simply used as a tool which allows one to pick up the magnetization of an arbitrary spin and to transfer it to a scalar-coupled partner. If the

signals overlap heavily, it is possible to use several consecutive transfer steps, so that the resolving power approaches that of three- or higher-dimensional spectroscopy.^{12,15,16}

5 USE IN SELECTIVE TWO-DIMENSIONAL SPECTROSCOPY

So far, the principle of doubly-selective Hartmann–Hahn transfer has found two distinct applications in the area of selective two-dimensional spectroscopy. It is possible to insert a Hartmann–Hahn transfer either in the preparation period or in the mixing interval. The first idea, which leads to a ‘Separation of Patterns by Lifting the Imbroglio of Transfer’ (SPLIT-COSY), is useful whenever two or more multiplets overlap in soft COSY spectra.¹⁷ Typically, such a situation arises when an A – X cross peak belonging to a network R overlaps with an A' – X' cross-peak arising from another network R' because the chemical shifts of A and A' on the one hand and of X and X' on the other are nearly or completely degenerate. The multiplets can easily be separated provided that there exists at least one passive coupling partner K or K' in one of the networks which does *not* suffer from overlap. In this case, selective excitation of transverse magnetization of K or K' can be followed by one or several consecutive,^{15,16} selective Hartmann–Hahn transfer steps so that one obtains in-phase magnetization of either of the nuclei A or A' . This is followed up by a normal soft COSY sequence (or, for that matter, by any other selective two-dimensional sequence), so that one can split overlapping patterns. An example is shown in Figure 4.

Figure 4 Separation of overlapping multiplets by SPLIT-COSY. Top: overlapping soft-COSY multiplets belonging to a mixture of *cis* (*c*)- and *trans* (*t*)-cyclopropane derivatives, due to coherence transfer from X^{cis} to A^{cis} and from X^{trans} to A^{trans} . Middle: SPLIT-COSY multiplet due to the *cis* isomer only, obtained by injecting magnetization from M^{cis} to X^{cis} in the preparation interval of the two-dimensional experiment. Bottom: SPLIT-COSY multiplet due to the *trans* isomer only, obtained by injection from M^{trans} to X^{trans} at the beginning of the evolution interval. (Reproduced by permission of Verlag Chemie from Vincent et al.¹⁷)

A more sophisticated application of selective Hartmann–Hahn transfer to two-dimensional spectroscopy is used in Pure In-phase Correlation SpectroscopyY (PICSY), where a doubly-selective irradiation is inserted in the mixing period.¹⁸ In this case, evolution under various scalar couplings leads to a manifold of antiphase terms at the beginning of the mixing period, some of which have to be eliminated by

Figure 5 Multiplets correlating the γ^{cis} and δ^{cis} protons of D-proline (Pro) in *cyclo*(L-Pro-L-Pro-D-Pro). (a) Experimental soft-COSY multiplet. (b) In-phase multiplet obtained by PICSY. suitable purging pulses. The resulting in-phase multiplets are particularly easy to analyze, since they do not suffer from cancelation of signals with opposite signs. The binomial rules that govern the amplitudes of multiplets are the same as in conventional one-dimensional spectra. An example is shown in Figure 5.

In conclusion, it appears that the selective transfer of magnetization by Hartmann-Hahn cross polarization in liquids opens a wide range of possibilities for the simplification of spectra and for the investigation of dynamic processes. The examples shown in the article are not intended to provide a complete overview.

1 INTRODUCTION

In 1985, Weitekamp envisioned a phenomenon wherein the singlet state nuclear spin order associated with parahydrogen (*p*-H₂) could be converted into observable nuclear spin magnetization.¹ In this effect, which was given the acronym PASADENA (Parahydrogen and Synthesis Allows Dramatically Enhanced Nuclear Alignment),² a highly ordered non-equilibrium nuclear spin state distribution is obtained on the product of a hydrogenation reaction with H₂ enriched in the *p*-H₂ mole fraction. The proposal, together with the density operator theory of the PASADENA phenomenon, was published in 1986,³ and the experimental demonstration came shortly thereafter.⁴ The PASADENA enhanced proton spectrum of propionitrile resulting from the Rh(I)(PPh₃)₃Cl catalyzed hydrogenation of acrylonitrile was shown to agree exactly with the density matrix simulation of the A₂X₃ proton spectrum. This was the first time a hydrogenation reaction had been knowingly conducted with the intention of converting the symmetrization order of para-enriched H₂ into enhanced NMR signals. Later that same year, Eisenshmid et al. confirmed the observation of the PASADENA effect in several other hydrogenation reactions.⁵ By this time, it was also recognized that there were several previous reports of unusual NMR signal enhancements in hydrogenation reactions under conditions that, by happenstance, were ideal for the observation of PASADENA signal enhancement.^{6–8} Understandably, the signals were in some cases misinterpreted as originating from a particular mechanism of chemically induced dynamic nuclear polarization (CIDNP).^{9,10} An interesting historical account on these events has appeared in the literature.¹¹

Since the original experimental demonstration of the PASADENA effect using Wilkinson's Catalyst, the phe-

nomenon has been confirmed with many other hydrogenation catalysts, including Rh₂H₂(CO)₂(dppm)₂ (dppm = bis(diphenylphosphino) methane),⁵ [Rh₃(CO)₂Cl₂H₂((Ph₂PCH₂)₂PPh)₂]⁺,⁵ Pd₂Cl₂ (dppm)₂,⁵ Rh(diphos)⁺ (diphos = bis(dephenylphosphino)ethane),¹² Ir(CO)(PPh)₂Cl (Vaska's catalyst),^{3,12} and others complexes of Rh, Ir, Ru, Pt, and Os.¹³ Furthermore, the basic PASADENA effect has been coupled to a variety of one and two-dimensional NMR pulse sequences.^{12–14} For example, the sharing of the *p*-H₂ singlet spin order with other nuclei (protons, ¹³C, ³¹P, ¹⁵N, etc.) via evolution under scalar or dipolar interactions has been demonstrated.¹⁵ The kinetics and mechanisms of several hydrogenation reactions has been investigated in detail using *p*-H₂ as a spin label. In some cases, new intermediates have been made observable as a result of the signal enhancement.^{12,16–18} PASADENA NMR spectroscopy has also been extended to two time dimensions for the purpose of probing chemical exchange and for mapping coupling connectivities.^{12–14}

Due to space limitations, it is possible to mention only a fraction of the examples of chemical applications and pulse sequences that have been developed over the past 15 years. Fortunately, there are several other reviews describing the chemical applications and pulse sequence methodology in *p*-H₂ enhanced NMR spectroscopy.^{13,14} The emphasis of this article is on the density operator/matrix theory of the PASADENA technique along with several demonstrative chemical applications. NMR signals are calculated for spin systems in the solution state and at a solid surface. Next, a brief review of the ALTADENA effect (Adiabatic Longitudinal Transport After Dissociation Engenders Net Alignment) will be presented. This is followed by a presentation of the theory for deuteron NMR enhancement by chemical addition of ortho-enriched D₂, where the ground rotational state corresponds to symmetric (ortho) nuclear spin states. Finally, the first experimental demonstration of proton NMR enhancement by the PASADENA effect at a surface is described.

2 NUCLEAR SPIN STATES OF H₂ AND D₂

2.1 Dihydrogen Wave Function

The total wave function of any homonuclear diatomic must be formulated in accordance with the Pauli Exclusion Principle which in essence states that the total wave function must be antisymmetric with respect to permutation of the nuclear labels in the case of half-integer nuclei, and symmetric for permutation of nuclei with integral or zero spin. For H₂ and D₂, the ground electronic state is ¹Σ_g⁺, a symmetric function with respect to inversion and reflection of the electronic coordinates. In the Born-Oppenheimer, rigid-rotor approximation, the overall wave function may be factored as follows:

$$\Psi_{\text{tot}} = \psi_e \psi_v \psi_r \psi_n \quad (1)$$

Consequently, the symmetries of the rotational and nuclear spin functions are correlated. In the case of H₂, the nuclear spin state must be symmetric when the molecule occupies an antisymmetric, odd *J*-valued rotational state. For *I* = 1/2, the nuclear spin triplet functions corresponding to the sum of

2 PHYSICAL APPLICATIONS

the angular momenta, $I_1 + I_2 = I = 1$, are symmetric, while the singlet spin state corresponding to $I_1 - I_2 = I = 0$ is antisymmetric. Hydrogen in the symmetric nuclear spin state is known as orthohydrogen ($o\text{-H}_2$), while parahydrogen ($p\text{-H}_2$) refers to molecules in the antisymmetric nuclear spin state:

$$|\psi_{\text{ortho}}\rangle = \begin{cases} |\beta\beta\rangle & m_1 = -1 \\ \frac{1}{\sqrt{2}}(|\alpha\beta\rangle + |\beta\alpha\rangle), & m_1 = 0 \text{ (odd } j) \\ |\alpha\alpha\rangle, & m_1 = +1 \end{cases} \quad (2)$$

$$|\psi_{\text{para}}\rangle = \frac{1}{\sqrt{2}}(|\alpha\beta\rangle - |\beta\alpha\rangle) \text{ (even } j) \quad (3)$$

These nuclear spin functions are eigenfunctions of the permutation operator $\hat{P}_n$ with eigenvalues of ± 1 : $\hat{P}_n \psi_n = \pm \psi_n$. In addition, the two states $\Psi_{\text{tot}}(1,2)$ and $\Psi_{\text{tot}}(2,1)$ are exchange degenerate since the total molecular Hamiltonian $\hat{H}$ is necessarily a symmetric operator. Thus, $\hat{H}\hat{P}\Psi_{\text{tot}} = \hat{P}\hat{H}\Psi_{\text{tot}}$ and the two operators commute: $[\hat{P}, \hat{H}] = 0$. Consequently the singlet and triplet nuclear spin states are also eigenfunctions of the nuclear spin Hamiltonian of the molecule. In its application to H_2 and D_2 , the Pauli Exclusion principle is responsible for the following properties:

- (1) Symmetry considerations based on symmetry lead to several remarkable features of H_2 and D_2 . These gases can exist in either of two distinct quasi-stable forms: the para (antisymmetric) and ortho (symmetric) nuclear spin states. Since transitions between singlet and triplet nuclear spin states are magnetic dipole forbidden, it is possible to prepare a quasi-stable nonequilibrium ortho-para H_2 mixture. It was Dennison who first realized that the interconversion of $o\text{-H}_2$ to $p\text{-H}_2$ was extremely slow in the absence of a catalyst.¹⁹
- (2) The degeneracy of the $o\text{-H}_2$ rotational levels is $3(2j + 1)$ while the degeneracy of the $p\text{-H}_2$ levels is $2j + 1$. As a result, the ortho:para ratio of an H_2 sample in the high temperature regime ($T \gg \theta_r$), referred to as $n\text{-H}_2$, approaches 3:1, while the ortho:para ratio of $n\text{-D}_2$ approaches 2:1.
- (3) At sufficiently low temperature ($T \leq \theta_r$ i.e., where θ is the characteristic temperature of rotation) there will be a substantial enrichment of $p\text{-H}_2$ (or $o\text{-D}_2$). The interconversion may be catalyzed by a paramagnetic solid such as activated charcoal²⁰ or iron filings. Commercial catalysts such as Apachi (a nickel silica gel) have been developed.²¹ The mechanism for interconversion depends on the type of catalyst. One mechanism involves chemisorption of H_2 to form atomic hydrogen. Spin-lattice relaxation, and subsequent recombination result in the thermal equilibrium mixture composition. Alternatively, the paramagnetic solid may provide field gradients on the molecular scale that break the magnetic equivalence of the protons, allowing the ortho-para transitions to become slightly allowed due to single-triplet mixing.
- (4) Once enriched at low temperature, the gas can be removed from the catalyst, warmed, and stored for days without significant reconversion. A convenient temperature at which to perform the enrichment is 77 K where the equilibrium $p\text{-H}_2$ mole fraction is $\chi_p = 0.51$ while the equilibrium $o\text{-D}_2$ mole fraction is $\chi_o = 0.70$. Thus, it is the rotational constant that determines the energy separation

of the $I = 0$ and $I = 1$ nuclear spin states in this strongly coupled spin system rather than differences in the nuclear Zeeman energy as is the usual case for nuclear spin systems in a molecule with symmetry number $\sigma = 1$.

The equilibrium ortho-para composition of H_2 or D_2 can be derived from the rigid rotor partition function. For H_2 , the ortho-para ratio is:

$$\frac{N_{\text{ortho}}}{N_{\text{para}}} = \frac{3 \sum_{j=1,3,\dots} (2j+1) e^{-\Theta_r j(j+1)/T}}{\sum_{j=0,2,\dots} (2j+1) e^{-\Theta_r j(j+1)/T}} \quad (4)$$

where $\Theta_R = \hbar^2/2kA$, $A = \mu r_{12}^2$ is the moment of inertia for the internuclear separation r_{12} , and $\mu = m_1 m_2 / (m_1 + m_2)$ is the reduced mass of the homonuclear diatomic molecule. The percentage composition of $p\text{-H}_2$ and $o\text{-H}_2$ is plotted in Figure 1. Since the characteristic temperature of rotation of H_2 is $\Theta_r = 85.3$ K, the low temperature regime (with respect to rotation) is relatively easy to access, and is well above the boiling point of the gas. It follows that thermal equilibration of a volume of H_2 gas at 77 K should produce an appreciable enrichment of the para spin isomer. Indeed, the percentage of molecules in the singlet nuclear spin state is 51% at this temperature (compared to approximately 25% at 300 K). One might expect a substantial enhancement of the NMR absorption signal following equilibration of the gas at 77 K. The problem is that the symmetrization order of the rotationally cooled gas is not observable by NMR because the singlet-triplet magnetic dipole transition is strictly forbidden. In fact, the only NMR signal that can be detected from the H_2 gas is due to transitions among the triplet states, but in this manifold, the Boltzmann factor is determined by the nuclear Zeeman interaction rather than the rotational splitting, yielding population differences on the order of only tens of parts per million at typical NMR fields. However, it turns out to be possible to transform the symmetrization order associated with $p\text{-H}_2$ into dramatic NMR signal enhancements if the molecule is deposited into a symmetry breaking magnetic environment

Figure 1 Percentage composition of $p\text{-H}_2$ or $o\text{-D}_2$ as a function of temperature

wherein the protons of the original H_2 molecule remain coupled. The analogous phenomenon is expected for D_2 .

2.2 Nuclear Spin Density Operator of H_2

The spin dynamics and NMR signal enhancement resulting from chemical addition of ortho/para H_2 or D_2 into a symmetry breaking magnetic environment is most conveniently investigated using density matrix or density operator methods. The H_2 density matrix for a sample with arbitrary ortho/para composition is readily constructed using the singlet/triplet nuclear spin eigenstates of equations (2) and (3). From this matrix, the density operator can be obtained and subjected to varying reaction conditions. Finally, the NMR observables can be calculated from the time evolution of the density operator according to the Liouville-von Neumann equation together with the standard trace relations for the complex transverse magnetization.

For an arbitrary ortho-para mixture with mole fraction χ_p of p - H_2 , the equilibrium density matrix in the singlet-triplet basis is

$$\rho = \begin{matrix} \Psi_{1,1} \\ \Psi_{1,0} \\ \Psi_{1,-1} \\ \Psi_{0,0} \end{matrix} \begin{bmatrix} (1-\chi_p)/3 & 0 & 0 & 0 \\ 0 & (1-\chi_p)/3 & 0 & 0 \\ 0 & 0 & (1-\chi_p)/3 & 0 \\ 0 & 0 & 0 & \chi_p \end{bmatrix} \quad (5)$$

The equilibrium density operator for the arbitrary ortho-para mixture may be written as:

$$\hat{\rho} = \frac{1}{4}\hat{1} - f\hat{\mathbf{I}}_1 \cdot \hat{\mathbf{I}}_2 \quad (6)$$

where $\hat{\mathbf{I}}_1$ and $\hat{\mathbf{I}}_2$ are the nuclear spin operators for each nucleus and $f = (4\chi_p - 1)/3$. In most applications, H_2 will be incorporated by chemical addition into a substrate nuclear spin system that is essentially disordered. Although there will be some equilibrium Curie-Law paramagnetism, this can usually be neglected. The density operator of the unpolarized substrate spin system (labeled 3..N) is:

$$\hat{\rho}^s = \prod_{i=3,N} \frac{\hat{1}}{d_i} \quad (7)$$

where $d_i = 2I_i + 1$ and the product is a tensor product. The tensor product is also used to construct the total spin system including the original H_2 and the substrate nuclei. Thus

$$\hat{\rho}^{\text{adduct}} = \hat{\rho}^{H_2} \otimes \hat{\rho}^s \quad (8)$$

The density operator resulting from H_2 addition serves as the initial condition for the ensuing spin dynamics due to radio frequency pulses and free evolution under the internal Hamiltonian.

Implicit in equation (8) is the chemically unrealistic assumption that the time of product formation is identical for all molecules in the sample. In most cases, there will be a distribution of formation times, and the form of the density matrix will depend on the details of the chemical kinetics and mechanism. To determine the response of the spin system, it is useful to transform the density matrix of the H_2 to the eigenbasis of the product spin system. These will be the eigenstates $|\psi_i\rangle$

satisfying $\hat{\mathcal{H}}_{\text{int}}|\psi_i\rangle = \varepsilon_i\hbar|\psi_i\rangle$ of the high field, rotating frame Hamiltonian $\hat{\mathcal{H}}_{\text{int}}$ consisting of chemical shifts, dipolar and J couplings. The diagonal elements of the density matrix in this basis have no time evolution, aside from spin-lattice relaxation, while the off-diagonal elements ρ_{ij} (i.e., coherences) oscillate at frequencies $(\varepsilon_j - \varepsilon_i)/\hbar$. To model a finite reaction rate, the density matrix resulting from hydrogenation must be averaged over the distribution of product formation times. If the reaction is slow such that the distribution of formation times is broad compared to the period of this oscillation, then the coherences will lose amplitude or even vanish due to destructive interference.

2.3 Nuclear Spin Density Operator of the Product Molecule

In general, the high speed spin Hamiltonian on the product molecule will consist of chemical shift, dipolar coupling and scalar coupling terms. The high-field, rotating-frame Hamiltonian for two spins-1/2 is:

$$\hat{\mathcal{H}}_{\text{int}} = \omega_{z1}\hat{I}_{z1} + \omega_{z2}\hat{I}_{z2} + D[\hat{\mathbf{I}}_1 \cdot \hat{\mathbf{I}}_2 - 3\hat{I}_{z1}\hat{I}_{z2}] + J\hat{\mathbf{I}}_1 \cdot \hat{\mathbf{I}}_2 \quad (9)$$

where ω_{z1} , ω_{z2} are the rotating frame chemical shifts of each spin, J is the scalar coupling constant, $D = (\omega_D/2)(3\cos^2\vartheta - 1)$ and $\omega_D = \gamma^2\hbar/r^3$. The eigenstates are:

$$|1\rangle = |\alpha\alpha\rangle \quad (10)$$

$$|2\rangle = c_1|\alpha\beta\rangle + c_2|\beta\alpha\rangle \quad (11)$$

$$|3\rangle = -c_2|\alpha\beta\rangle + c_1|\beta\alpha\rangle \quad (12)$$

$$|4\rangle = |\beta\beta\rangle \quad (13)$$

where $c_1 = \cos(\kappa/2)$, $c_2 = \sin(\kappa/2)$ and $\tan(\kappa) = (D + J)/\Delta\omega_z$. The parameters $\bar{\omega} = 1/2(\omega_{z1} + \omega_{z2})$ and $\Delta\omega_z = \omega_{z1} - \omega_{z2}$ are the average chemical shift and chemical shift difference, respectively. The dipolar interaction depends on the angle ϑ between the internuclear vector and the applied field. In general the chemical shifts $\omega_{zi}(\vartheta, \phi, \Omega_i)$ depend on the Euler angles $\Omega_i = \{\alpha_i, \beta_i, \gamma_i\}$ relating the principal axis system of the chemical shift to that of the dipolar interaction. The orientation dependence of the chemical shifts and dipolar coupling introduces distinct spectral features for solid or surface bound nuclei, as will be explored in Section 8. For a liquid sample, the rapid reorientation of the spin system reduces the tensorial spin interactions to their isotropic values. The angle κ specifies the strength of the coupling. For weak coupling, $\Delta\omega_z \gg \{J, D\}$, $\kappa \rightarrow 0$ and the simple product states $|\alpha\alpha\rangle$, $|\alpha\beta\rangle$, $|\beta\alpha\rangle$, and $|\beta\beta\rangle$ are recovered. The singlet-triplet states are obtained in the strong coupling limit, where $\kappa \rightarrow \pi/2$. These are the same nuclear spin states as in the original H_2 molecule.

3 GENERAL THEORY OF THE PASADENA EFFECT

3.1 The Sudden Approximation

When the protons of H_2 are deposited into magnetically inequivalent sites of the product molecule, the internal Hamiltonian of the 2-spin system suddenly changes. The given initial state $|\psi_i\rangle$ will continue to describe the quantum state of

the system even though it is not necessarily an eigenstate of the product molecule Hamiltonian. According to the sudden approximation, the transition probability from an initial state $|\psi_i\rangle$ to a final state $|\psi_f\rangle$ may be calculated from the square of the projection of $|\psi_i\rangle$ onto $|\psi_f\rangle$:

$$p_{fi} = |\langle\psi_f|\psi_i\rangle|^2. \quad (14)$$

The transition probabilities from singlet H_2 , where $|\psi_i\rangle = 2^{-1/2}(|\alpha\beta\rangle - |\beta\alpha\rangle)$ to the final states, $|1\rangle$, $|2\rangle$, $|3\rangle$ and $|4\rangle$ given in equations (10)–(13), are:

$$\begin{aligned} p_1 &= \frac{1}{2} \langle 1|\alpha\beta - \beta\alpha\rangle = 0 \\ p_2 &= \frac{1}{2} \langle 2|\alpha\beta - \beta\alpha\rangle = \frac{1}{2}(1 - \sin\kappa) \\ p_3 &= \frac{1}{2} \langle 3|\alpha\beta - \beta\alpha\rangle = \frac{1}{2}(1 + \sin\kappa) \\ p_4 &= \frac{1}{2} \langle 4|\alpha\beta - \beta\alpha\rangle = 0 \end{aligned} \quad (15)$$

These transition probabilities determine the population distribution of the final states. The resultant nuclear spin density matrix summarizes the state of the ensemble of spin systems formed by the instantaneous reaction of H_2 of arbitrary ortho-para composition. In the basis set $|1\rangle$, $|2\rangle$, $|3\rangle$ and $|4\rangle$ [equations (10)–(13)], the density matrix of the adduct is

$$\rho^{\text{adduct}} \rightarrow \begin{bmatrix} \frac{1-f}{4} & 0 & 0 & 0 \\ 0 & \frac{1+f}{4} - \frac{f}{2}\sin\kappa & \frac{f\cos\kappa}{2} & 0 \\ 0 & \frac{f\cos\kappa}{2} & \frac{1+f}{4} + \frac{f}{2}\sin\kappa & 0 \\ 0 & 0 & 0 & \frac{1-f}{4} \end{bmatrix} \quad (16)$$

There are several noteworthy features of this density matrix.

- Notice that the reaction of pure $p\text{-H}_2$, where $\chi_p = 1$ and $f = (4\chi_p - 1)/3 \rightarrow 1$, leads to the population of states $|2\rangle$ and $|3\rangle$ but not $|1\rangle$ and $|4\rangle$, with the branching ratio dependent upon the coupling strength parameter κ . The reaction with pure $o\text{-H}_2$ ($\chi_p = 0$) yields population of all four states, but with greater population of the outer states $|1\rangle$ and $|4\rangle$. The population distributions resulting from each of these two cases is illustrated in Figure 2.
- The reaction with $n\text{-H}_2$, where $\chi_p = 1/4$, leads to equal population of all 4 states. This case is illustrated by combining the population distribution resulting from $p\text{-H}_2$ and $o\text{-H}_2$, as is evident in Figure 2.
- Nuclear spin coherences are also created, with the amplitude depending on κ . In the weak coupling limit the coherences may be identified as pure zero quantum transitions ($|\alpha\beta\rangle \leftrightarrow |\beta\alpha\rangle$).

3.2 Time Evolution of the Adduct Density Matrix

Neglecting spin relaxation, the time evolution of the density matrix is obtained by solving the Liouville-von Neumann equation. With energies expressed in units of frequency (we take $\hbar = 1$),

$$\frac{d}{dt}\hat{\rho}(t) = -i[\hat{\mathcal{H}}(t), \hat{\rho}(t)] \quad (17)$$

This has the formal solution

$$\hat{\rho}(t) = \hat{U}(t)\hat{\rho}(0)\hat{U}^\dagger(t) \quad (18)$$

where

$$\hat{U}(t) = \hat{T} \exp \left\{ -i \int_0^t \hat{\mathcal{H}}(t') dt' \right\} \quad (19)$$

and $\hat{T}$ is the Dyson time-ordering operator. When $\hat{\mathcal{H}}$ is time-independent, or if the evolution can be broken down into periods which are piecewise time-independent, the propagator

Figure 2 Correlation diagram for the nuclear spin states resulting from dihydrogen addition in the PASADENA effect. Starting with 2 moles of parahydrogen (left), the addition into weakly coupled, chemically inequivalent sites leads to 1 mole in each of the two middle states ($|\alpha\beta\rangle$ and $|\beta\alpha\rangle$). Starting with 6 moles of orthohydrogen (right), the result is 2 moles in each of the outer states and 1 mole in the middle two states. Starting with 8 moles of hydrogen initially equilibrated at high temperature, the resulting populations would be the combination of hollow and filled circles: the four states would be equally populated with two moles in each

can be factored. For example, the evolution over two periods t_1 and t_2 may be written as

$$\hat{\rho}(t_0 + t_1 + t_2) = e^{-i\hat{H}_2 t_2} e^{-i\hat{H}_1 t_1} \hat{\rho}(t_0) e^{-i\hat{H}_1 t_1} e^{i\hat{H}_2 t_2} \quad (20)$$

The time dependence of any expectation value may be calculated from the trace of the product of $\hat{\rho}(t_0 + t_1 + t_2)$ with the appropriate observable operator. For example, the observed rotating frame NMR signal is proportional to the complex transverse magnetization, which is proportional to $\langle \hat{I}_+ \rangle$:

$$\begin{aligned} S(t) &= \text{Tr}\{\hat{I}_+ e^{-i\hat{H}t} \hat{\rho}(t=0) e^{i\hat{H}t}\} \\ &= \sum_{m,n} \langle m | \hat{I}_+ | n \rangle \langle n | e^{-i\hat{H}t} \hat{\rho}(t=0) e^{i\hat{H}t} | m \rangle \\ &= \sum_{m,n} \langle m | \hat{I}_+ | n \rangle \langle n | \hat{\rho}(t=0) | m \rangle e^{-i\omega_{mn}t} \end{aligned} \quad (21)$$

The summation is over the basis states of the matrix representation. The ω_{mn} are the single quantum transition frequencies. For example, the $|1\rangle \rightarrow |2\rangle$ transition frequency is

$$\omega_{12} = \bar{\omega} - D + \frac{J}{2} - \frac{1}{2}(\Delta\omega_z^2 + (D + J)^2)^{1/2} \quad (22)$$

3.3 Density Matrix Averaged Over Product Formation Times

As was shown in Section 3.1, the sudden change that occurs upon H_2 addition results in a superposition of states $|2\rangle$ and $|3\rangle$ which is generally not an eigenfunction of the product molecule spin Hamiltonian. In the weak coupling limit, this superposition corresponds to a zero quantum transition, $|\alpha\beta\rangle \rightarrow |\beta\alpha\rangle$, with a Bohr frequency $\omega_{23} = [(J + D)^2 + \Delta\omega_z^2]^{1/2}$. If the distribution of product formation times is relatively long compared to $2\pi/\omega_{23}$, then the off-diagonal elements $f \cos \kappa/2$ of the density matrix (equation (16)) will vanish upon averaging over the distribution of product formation times, yielding

$$\langle \hat{\rho}^{\text{adduct}} \rangle = \begin{bmatrix} \frac{1-f}{4} & 0 & 0 & 0 \\ 0 & \frac{1+f}{4} - \frac{f}{2} \sin \kappa & 0 & 0 \\ 0 & 0 & \frac{1+f}{4} + \frac{f}{2} \sin \kappa & 0 \\ 0 & 0 & 0 & \frac{1-f}{4} \end{bmatrix} \quad (23)$$

For analytical calculations of the FID, it is convenient to express this diagonal density matrix in operator form:

$$\begin{aligned} \langle \hat{\rho}^{\text{adduct}} \rangle &= \frac{1}{4} \hat{1} - f \left\{ \frac{1}{2} \sin \kappa \cos \kappa (\hat{I}_{z1} - \hat{I}_{z2}) \right. \\ &\quad \left. + \frac{1}{3} \cos^2 \kappa (3\hat{I}_{z1} \hat{I}_{z2} - \hat{\mathbf{I}}_1 \cdot \hat{\mathbf{I}}_2) \right. \\ &\quad \left. + \left[1 - \frac{2}{3} \cos^2 \kappa \right] \hat{\mathbf{I}}_1 \cdot \hat{\mathbf{I}}_2 \right\} \end{aligned} \quad (24)$$

3.4 Calculation of the NMR Signal

Having derived the two-spin density operator and density matrix following hydrogenation of a substrate, the next step is to calculate the free induction decay signal. Inspection of the density operator reveals that only the first two terms in brackets in equation (24) can lead to transverse magnetization following a single rf pulse. The third term contains the scalar operator $\hat{\mathbf{I}}_1 \cdot \hat{\mathbf{I}}_2$ that is invariant to rotations. Applying an rf pulse with tip angle θ yields the following expression for the density operator, where only single quantum coherences are retained:

$$\begin{aligned} \langle \hat{\rho} \rangle_{\text{SQ}}(\theta) &= f \left\{ \frac{1}{2} \sin \kappa \cos \kappa \sin \theta (\hat{I}_{x2} - \hat{I}_{x1}) \right. \\ &\quad \left. - \cos^2 \kappa \sin \theta \cos \theta (\hat{I}_{z1} \hat{I}_{x2} + \hat{I}_{x1} \hat{I}_{z2}) \right\} \end{aligned} \quad (25)$$

The NMR signal is calculated using the trace formula [equation (21)].

$$\begin{aligned} S(t, \kappa) &= \frac{f}{4} \cos^2 \kappa \sin \theta \{ (-\cos \theta + \sin \kappa - \cos \theta \sin \kappa) e^{-i\omega_{12}t} \\ &\quad + (-\cos \theta - \sin \kappa + \cos \theta \sin \kappa) e^{-i\omega_{13}t} \\ &\quad + (\cos \theta - \sin \kappa + \cos \theta \sin \kappa) e^{-i\omega_{24}t} \\ &\quad + (\cos \theta + \sin \kappa - \cos \theta \sin \kappa) e^{-i\omega_{34}t} \} e^{-t/T_2} \end{aligned} \quad (26)$$

A phenomenological damping factor has been appended to account for transverse spin relaxation. Spectra corresponding to the Fourier transform of this signal expression are plotted in Figure 3 for $D = 0$ and for varying coupling strengths, as determined by the chemical shift to J -coupling ratio, $\Delta\omega_z/J$. The spectra were plotted for two different pulse angles: $\theta = \pi/2$ and $\theta = \pi/4$. For reference, the figure also includes the conventional NMR spectra derived from Zeeman order due to thermal polarization within the high temperature approximation.

3.5 NMR Enhancement Factor

To quantify the signal enhancement resulting from p - H_2 addition it is useful to relate the signal amplitudes to a reference. Two meaningful choices are the NMR signals arising from a hypothetical sample at 0 K and a sample at thermal equilibrium at 300 K. At 0 K only the $|\alpha\alpha\rangle$ state is populated. The two-spin density operator is a linear combination of scalar, Zeeman and dipolar order, as follows:

$$\hat{\rho}_{\text{eq}} = \frac{1}{4} \hat{1} + a \hat{\mathbf{I}}_1 \cdot \hat{\mathbf{I}}_2 + b \hat{I}_z + c (3\hat{I}_{z1} \hat{I}_{z2} - \hat{\mathbf{I}}_1 \cdot \hat{\mathbf{I}}_2) \quad (27)$$

If a $\pi/2$ pulse is applied, only the Zeeman order ($b \hat{I}_z$) produces detectable transverse magnetization, so only this term needs to be retained in the signal calculation. At any temperature, application of a $\pi/2$ pulse yields

$$\begin{aligned} S_{\text{eq}}(t, \kappa) &= \frac{b(T)}{2} \{ (1 + \sin \kappa) (e^{-i\omega_{12}t} + e^{-i\omega_{24}t}) + (1 - \sin \kappa) \\ &\quad \times (e^{-i\omega_{13}t} + e^{-i\omega_{34}t}) \} \end{aligned} \quad (28)$$

Figure 3 Two spin simulations as a function of the ratio $\Delta\omega_z/J$ using two pulse angles θ : column (b) $\theta = \pi/4$ and column (c) $\theta = \pi/2$. Column (a) is the spectrum obtained from Zeeman order pertaining to thermal polarization of the spin system in the high temperature limit

The enhancement factor is defined as the ratio of the signal intensities for a specified transition. The theoretical ratio of the amplitudes of the ω_{12} transition is

$$\frac{S_{\text{PAS}}}{S_{\text{eq}}} = \frac{f \cos^2 \kappa \sin \theta [\sin \kappa - \cos \theta - \cos \theta \sin \kappa]}{2[1 + \sin \kappa]b(T)} \quad (29)$$

At 0 K the coefficient $b(0\text{ K}) = 1/2$ can be determined using the fact that at this temperature the spins are completely ordered and the density operator is simply $\hat{\rho}(0\text{ K}) = |\alpha\alpha\rangle\langle\alpha\alpha|$.

$$\text{Tr}\{\hat{I}_z \hat{\rho}(0\text{ K})\} = 1 = b(0\text{ K}) \text{Tr}\{\hat{I}_z^2\} = 2b(0\text{ K}) \quad (30)$$

Substitution into equation (29) shows that the theoretical signal obtained from 100% $p\text{-H}_2$ with a $\theta = \pi/4$ pulse in the weak-coupling limit ($\kappa \rightarrow 0$) is exactly half the maximum possible signal obtained from the hypothetical sample at 0 K.

In the high temperature regime,

$$b(T) = \frac{\gamma \hbar H_0}{kT(2I + 1)^N} \quad (31)$$

In comparison to the theoretical signal amplitude in the weak-coupling limit with $\theta = \pi/4$ at $T = 300\text{ K}$ and $H_0 = 4.7\text{ T}$ (200 MHz ^1H), the enhancement numerically evaluates to $31\,240 \cdot f$.

4 PASADENA EFFECT IN WEAKLY COUPLED SPIN SYSTEMS

To extend the discussion of proton signal enhancement by $p\text{-H}_2$ addition to a great variety of experiments involving molecules in liquid solution, progress can be made by restricting the PASADENA theory to weakly coupled spin systems, where the Hamiltonian becomes

$$\hat{\mathcal{H}}_{\text{int}} = \sum_{i < j}^N J_{ij} \hat{I}_{zi} \cdot \hat{I}_{zj} + \sum_i^N \omega_{zi} \hat{I}_{zi} \quad (32)$$

Two spins are said to be weakly coupled when $\Delta\omega_z \gg J$. Thus, according to equations (10)–(13), $\kappa \rightarrow 0$, and the eigenfunctions become the direct product functions. Restriction to weak coupling permits the use of the product operator formalism^{22,23} which has the advantage of preserving operator properties (and the physical meaning associated with them) throughout the calculation of the time evolution of the spin system.

4.1 Creation of Coherence from J -Order

The time averaged density operator of a weakly coupled two spin adduct formed using an arbitrary ortho-para H_2 mixture is:

$$\hat{\rho}(0) = \frac{1}{4} \hat{1} - f \hat{I}_{z1} \hat{I}_{z2} \quad (33)$$

Application of a y -phase rf pulse with tip angle θ transforms the density operator as follows:

$$\begin{aligned} \hat{\rho}(0) \xrightarrow{\theta \hat{I}_y} & \frac{1}{4} - f \cos^2 \theta \hat{I}_{z1} \hat{I}_{z2} - f \sin^2 \theta \hat{I}_{x1} \hat{I}_{x2} \\ & - f \sin \theta \cos \theta (\hat{I}_{z1} \hat{I}_{x2} + \hat{I}_{x1} \hat{I}_{z2}) \end{aligned} \quad (34)$$

This expression illustrates that a single rf pulse creates zero, single and double quantum coherences from the initial density operator. The last term corresponds to bilinear single quantum coherence that is optimized by a $\theta = \pi/4$ pulse. Such operators require a J -coupling and a chemical shift difference (or other form of magnetic inequivalence) to evolve into detectable signal. The $\hat{I}_{x1} \hat{I}_{x2}$ term commutes with the J -coupling interaction, and therefore, the $p = 0, \pm 2$ quantum coherences evolve only under the influence of the sum and difference of the rotating frame chemical shifts. For more than two spins, not all couplings will commute, giving rise to J -coupling structure in the $p = 0, \pm 2$ quantum transitions. While the zero and double quantum transitions are not directly observable, they can be useful in the context of 2D pulse sequences such as the chemical exchange sequence described in Section 5.2.6.

The overall time evolution of the density operator (equation (34)) under the internal Hamiltonian in equation (32) is

$$\hat{\rho}(0) \xrightarrow{\theta \hat{I}_y} \frac{1}{4} - f \cos^2 \theta \hat{I}_{z1} \hat{I}_{z2} \quad \text{populations} \quad (35)$$

$$- \frac{f}{4} \sin^2 \theta \{ \hat{I}_{-1} \hat{I}_{+2} \exp(2i \Delta\omega_z t) + \hat{I}_{+1} \hat{I}_{-2} \exp(-2i \Delta\omega_z t) \} \quad \text{ZQC} \quad (36)$$

$$-\frac{f}{4} \sin^2 \theta \{ \hat{I}_{+1} \hat{I}_{+2} \exp(2i\omega t) + \hat{I}_{-1} \hat{I}_{-2} \exp(-2i\omega t) \} \quad \text{DQC} \quad (37)$$

$$\begin{aligned} & -\frac{f}{2} \sin \theta \cos \theta \left\{ \cos \omega_{z2} t \left[2 \cos \frac{Jt}{2} \hat{I}_{z1} \hat{I}_{x2} - \sin \frac{Jt}{2} \hat{I}_{y2} \right] \right. \\ & - \sin \omega_{z2} t \left[2 \cos \frac{Jt}{2} \hat{I}_{z1} \hat{I}_{y2} - \sin \frac{Jt}{2} \hat{I}_{x2} \right] \quad \text{SQC} \\ & + \cos \omega_{z1} t \left[2 \cos \frac{Jt}{2} \hat{I}_{x1} \hat{I}_{z2} - \sin \frac{Jt}{2} \hat{I}_{y1} \right] \\ & \left. - \sin \omega_{z1} t \left[2 \cos \frac{Jt}{2} \hat{I}_{y1} \hat{I}_{z2} - \sin \frac{Jt}{2} \hat{I}_{x1} \right] \right\} \quad (38) \end{aligned}$$

4.2 A₂X₃ PASADENA Spectrum – Product Operator Treatment

Section 5 will present the results of PASADENA experiments involving the catalytic hydrogenation of styrene to ethylbenzene and acrylonitrile to propionitrile. Both product molecules may be described as weakly coupled A₂X₃ spin systems (including the two protons originally in the H₂ molecule, but ignoring the uninvolved aromatic group protons in the case of ethylbenzene). Therefore, the product operator description of the PASADENA effect for the A₂X₃ case will be given special consideration here.

The NMR signals resulting from either PASADENA spin order or conventional thermal spin polarization of the A₂X₃ system may be derived using the product operator treatment together with the following expansions for the trigonometric functions of spin operators for the AX₂ and AX₃ cases:

AX₂: Let $\hat{I}_a = \hat{I}_{a1} + \hat{I}_{a2}$, where $a = x, y$, or z

$$\cos(\chi \hat{I}_a) = \cos^2\left(\frac{\chi}{2}\right) - 4\hat{I}_{a1}\hat{I}_{a2} \sin^2\left(\frac{\chi}{2}\right)$$

$$\sin(\chi \hat{I}_a) = \hat{I}_a \sin \chi$$

AX₃: Let $\hat{I}_a = \hat{I}_{a1} + \hat{I}_{a2} + \hat{I}_{a3}$, where $a = x, y$, or z

$$\begin{aligned} \cos(\chi \hat{I}_a) &= \cos^3\left(\frac{\chi}{2}\right) - 4(\hat{I}_{a1}\hat{I}_{a2} + \hat{I}_{a1}\hat{I}_{a3} + \hat{I}_{a2}\hat{I}_{a3}) \\ &\quad \times \sin^2\left(\frac{\chi}{2}\right) \cos\left(\frac{\chi}{2}\right) \end{aligned}$$

$$\sin(\chi \hat{I}_a) = 2\hat{I}_a \sin\left(\frac{\chi}{2}\right) \cos^2\left(\frac{\chi}{2}\right) - 8\hat{I}_{a1}\hat{I}_{a2}\hat{I}_{a3} \sin^3\left(\frac{\chi}{2}\right)$$

According to the high temperature approximation, the traceless part of the initial density operator used to compute the conventional NMR signal consists of Zeeman order; $\hat{\rho}_{\text{eq}} \propto b(\hat{I}_{za} + \hat{I}_{zb})$, where the subscripts a and b denote magnetically equivalent groups of three and two spins, respectively; $\hat{I}_{za} = \hat{I}_{z1} + \hat{I}_{z3} + \hat{I}_{z5}$ and $\hat{I}_{zb} = \hat{I}_{z2} + \hat{I}_{z4}$. The time-domain NMR signal obtained from thermal equilibrium Zeeman order in the high temperature regime is:

$$S_{\text{eq}}(t) = 8b(T) \left\{ 3 \cos^2 \frac{Jt}{2} e^{i\omega_{zA}t} + 2 \cos^3 \frac{Jt}{2} e^{i\omega_{zB}t} \right\} \quad (39)$$

The amplitude factor $b(0 \text{ K})$ is calculated following the same procedure used in the two-spin case (Section 3.5). The result is

$$b(0 \text{ K}) = \frac{\text{Tr}(\hat{I}_z |\alpha\alpha\alpha\alpha\rangle \langle \alpha\alpha\alpha\alpha|)}{5 \text{Tr}(\hat{I}_{z1}^2)} = \frac{1}{16}$$

The absolute transition amplitudes of the methyl triplet and methylene quartet at 0 K are therefore $\{3/8, 3/4, 3/8\}$ and $\{1/8, 3/8, 3/8, 1/8\}$, respectively. The relative amplitudes of the A₂X₃ PASADENA signal can be derived from the PASADENA signal calculation or else by direct extension of the two-spin theory. The methyl group yields $\{f/8, 0, -f/8\}$, while the methylene protons yield $\{f/16 : f/16 : -f/16 : -f/16\}$. If the J -coupling is not fully resolved, the ideal intensity ratios may be distorted by interference effects that can lead to partial cancellation of intensity, especially for the inner lines of the multiplet transition. For this reason, the outer lines are used to compute the enhancement factor. The calculated numerical value of the enhancement factor of the PASADENA signal over the conventional signal obtained at 300 K is:

$$\frac{|S_{\text{PAS}}|}{|S_{\text{eq}}(300 \text{ K})|} = \frac{|S_{\text{PAS}}|}{|S_{\text{eq}}(0 \text{ K})|} \times \frac{|b(0 \text{ K})|}{|b(300 \text{ K})|} = 20\,800 \cdot f$$

The reduced enhancement relative to the 2-spin case is due to the dilution of the spin order of p -H₂ by the unpolarized protons of the substrate. The spin order of the incoming protons is shared among the nuclei of the magnetically equivalent groups due to bilinear cross polarization.

4.3 Evolution of Coherences Induced by Rapid Addition of p -H₂

When the time-scale of the chemical reaction is short compared to the period of the spin coherences initiated upon incorporation of H₂ into the substrate, the off-diagonal elements of the density operator represented by $\hat{I}_{x1}\hat{I}_{x2} + \hat{I}_{y1}\hat{I}_{y2}$ do not vanish. Since $[\hat{\mathcal{H}}_{\text{int}}, \hat{I}_1 \cdot \hat{I}_2] \neq 0$, the density operator becomes time dependent during the period before the rf read pulse.

$$\begin{aligned} \hat{\rho}(t_r) &= \frac{1}{4} - \hat{I}_{z1}\hat{I}_{z2} - (\hat{I}_{x1}\hat{I}_{x2} + \hat{I}_{y1}\hat{I}_{y2}) \cos(\Delta\omega_z t_r) \\ &\quad + (\hat{I}_{x1}\hat{I}_{y2} - \hat{I}_{y1}\hat{I}_{x2}) \sin(\Delta\omega_z t_r) \end{aligned} \quad (40)$$

Application of the θ angle pulse followed by further free evolution and detection gives the signal during t_2 :

$$\begin{aligned} S(t_r, \theta, t_2) &= -\frac{1}{8} \{ (a - ib) [\exp(i(\omega_{z1} + J/2)t_2) \\ &\quad - \exp(i(\omega_{z1} - J/2)t_2)] \\ &\quad - (a + ib) [\exp(i(\omega_{z2} + J/2)t_2) \\ &\quad - \exp(i(\omega_{z2} - J/2)t_2)] \} \end{aligned} \quad (41)$$

where $a = 2 \sin \theta \sin(\Delta\omega_z t_r)$ and $b = \sin 2\theta (1 - \cos(\Delta\omega_z t_r))$. The amplitude of the observed response is a function of t_r . The total signal energy is proportional to the integral of the modulus squared of the free induction decay:

$$E(t_r, \theta) \propto \int_0^\infty |S(t_r, \theta, t_2)|^2 dt_2 \quad (42)$$

It is convenient to reference the PASADENA signal energy to the signal energy that would be obtained from a fully polarized product molecule using a 90° detection pulse. The

dimensionless ratio R for a two spin system, obtained using equation (41), is

$$R(t_r) = \frac{E(t_r)}{E_0} = \frac{1}{4} \{ 4 \sin^2 \theta \sin^2 \Delta \omega_z t_r + \sin^2 2\theta [1 - \cos \Delta \omega_z t_r]^2 \} \quad (43)$$

This function is plotted for $N = 2$ spins in Figure 4(a). The dashed horizontal line in this plot indicates the level expected when the ensemble of product molecules is formed incoherently. The results of a numerical density matrix calculation of the ratio $R(t_r)$ for product molecules with $N = 3$ is shown in Figure 4(b). Notice that in all cases, the chemical shift difference is important in that it breaks the symmetry during t_r , allowing escape from the singlet state. However, in the weak-coupling limit, the J -coupling sets the timescale for development of signal.

4.4 Bilinear Cross Polarization

While the spin order associated with the protons originating on p -H₂ may be distributed to other magnetically equivalent nuclei in the adduct molecule due to the scalar coupling

Figure 4 Calculated dependence (see equation (43)) of the signal energy on the delay between the reaction (assumed instantaneous) and a $\pi/4$ rf pulse. (a) $N = 2$, *cis*-1-deuterio-2-bromethylene ($J_{12}/2\pi = 7.2$ Hz, $\nu_{z1} = -132$ Hz, $\nu_{z2} = 112$ Hz); (b) $N = 3$, bromoethylene ($J_{12}/2\pi = 7.2$ Hz, $J_{13}/2\pi = 15.0$ Hz, $J_{23}/2\pi = -1.7$ Hz, $\nu_{z1} = 112$ Hz, $\nu_{z2} = -132$ Hz, $\nu_{z3} = -200$ Hz). The chemical shifts correspond to a proton Larmor frequency at 500 MHz. Trace (b) was calculated by a numerical density matrix simulation. The vertical scales are relative to the signal energies that would be seen for perfect nuclear paramagnetic ordering subjected to a $\pi/2$ pulse. The dashed lines indicate the level expected when the ensemble of product molecules is formed incoherently

with them, a magnetically inequivalent spin may not receive polarization through this mechanism since the scalar coupling is truncated. As an example, Figure 5(a) shows a density matrix simulation of the PASADENA magnitude spectrum for bromoethylene formed by hydrogenation with p -H₂. In this simulation, the time-averaged initial density matrix, with off-diagonal elements set to zero, has been subjected to a 45° pulse. Notice that transitions involving the third proton, *cis* to Br, are absent.³

In many applications it will be desirable to transfer the p -H₂ spin order to other spins to enhance the signal of a larger number of site-specific resonances. The sequence shown below serves this purpose. In this sequence, $\mathbf{R}$ may represent a nutation pulse or a multiple pulse train such as a series of π pulses having the effect of averaging away the chemical shifts.^{24,25}

Figure 5 Bilinear cross polarization on bromoethylene. (a) The magnitude spectrum without cross polarization ($t_1 = 0$ in Figure 5c). (b) The corresponding spectrum with $t_1 = 131.2$ ms, at which time the multiplet due to H₃ (*cis* to Br) has grown to a maximum at the expense of resonances due to the protons originating on p -H₂. (c) The signal energy of this H₃ multiplet as a function of t_1 . The pulse sequence during t_1 consisted of repetitions of a train of 25 contiguous phase-shifted π -pulses, each pulse of length 64 ms

The spectrum of Figure 5(b) was obtained by simulating the application of a π pulse train for a time $t_1 = 131.2$ ms followed by a $\pi/4$ read pulse. The simulation demonstrates that the intense non-equilibrium magnetization is now shared with the third proton. The dependence of the signal energy of this new multiplet on the cross-polarization time t_1 is shown in Figure 5(c). The plotted quantity $R_3(t_1)$ is analogous to the energy ratio introduced in equation (43), but here the ratio refers to the multiplet of the third (magnetically inequivalent) proton. The sharing of spin-order occurs prior to any development of magnetization.

5 EXPERIMENTAL PASADENA NMR SPECTROSCOPY IN LIQUIDS

5.1 Experimental Apparatus

The simplest procedure for observing NMR signal enhancements by the PASADENA effect is to pressurize an NMR tube containing a premixed solution of the substrate and hydrogenation catalyst with p - H_2 gas. The hydrogenation reaction is initiated by shaking the tube followed by immediate insertion into the NMR probe to observe the enhanced signal. In the weak-coupling limit, the PASADENA signal is maximized using a $\pi/4$ pulse rather than the usual $\pi/2$ pulse. The reaction essentially stops once the dissolved H_2 has been consumed, since dissolution across the gas-liquid interface is slow. By ejecting the tube, shaking, and reinserting, additional enhanced spectra can be acquired using the same sample. However, caution be exercised in this method because net alignment of the multiplet signals may result from the adiabatic longitudinal transport of the spin order generated while the sample is at zero or low magnetic field. This is the ALTADENA effect which will be reviewed in Section 6.

An improved method providing a more controlled, repeatable and reproducible aliquot of p - H_2 employs the in-situ reaction apparatus shown in Figure 7. To produce a continuous stream of para-enriched H_2 for stopped-flow kinetic and 2D PASADENA NMR experiments, the gas is passed through a column packed with Apachi nickel silica gel catalyst.²¹ Before use, the coil is purged at room temperature with a stream of H_2 for a period of about one hour. Following the purge, the glass coil is immersed in liquid nitrogen. Solenoid valves are used to gate p - H_2 gas flow. Bubbles are produced by a glass capillary inserted into the reaction solution contained in the standard 5 mm NMR tube, as shown in the figure. The apparatus shown here produced a consistent and well-defined burst of H_2 through the solution. This is a critical requirement for stopped-flow kinetics studies as well as 2D PASADENA experiments that are susceptible to T_1 noise

contributions due to variations in the amount of product magnetization formed per H_2 burst. The system shown in Figure 7 has the added advantage of being closed to the external atmosphere, reducing the problem of catalyst poisoning by air. A disadvantage of this apparatus is that does not allow the tube to spin. If sample spinning to improve resolution is desired, the capillary can be inserted into an open NMR tube with no physical connection to the tube. With careful alignment of the capillary it proved possible to spin the NMR tube at 15 Hz.

5.2 Applications

When evaluating the potential applicability of PASADENA to the study of a specific hydrogenation reaction, one must keep in mind that the following two conditions need to be fulfilled in order to observe NMR signal enhancements:

- (1) The reaction must be molecular, so that the two protons of the original hydrogen molecule are transferred pairwise into magnetically inequivalent sites on the product. A resolved spin-spin coupling between these nuclei is also required.
- (2) The time-scale of the molecular addition should be short compared to the T_1 on the hydrogenation product. If a stepwise reaction mechanism is involved, the lifetime of any intermediate species should be short compared to the T_1 on each species.

Fortunately, there are a large variety of transition metal complexes that function as efficient hydrogenation catalysts in liquids at ambient temperature and pressure.

5.2.1 Hydrogenation of Acrylonitrile to Propionitrile by Wilkinson's Catalyst

Perhaps the best known homogeneous hydrogenation catalyst is $Rh(PPh_3)_3Cl$, Wilkinson's catalyst.²⁶ It was this particular catalyst that was used in the original experimental demonstration of the PASADENA effect.⁴ Para-enriched H_2 was added to acrylonitrile to form propionitrile, as follows:

The reaction was carried out with H_2 that had been equilibrated for approximately one-half hour at 77 K in the presence of Apachi,²¹ yielding 50% p - H_2 . The proton NMR spectrum of the d-chloroform solution containing the acrylonitrile substrate and catalyst was recorded prior to adding any H_2 , as shown in Figure 6(a). The p - H_2 was then bubbled for about 1 s through the d-chloroform solution containing the substrate and catalyst. Following a delay of about 1 s to allow the solution to settle, a single hard $\pi/4$ pulse was applied. The resulting PASADENA enhanced spectrum is shown in Figure 6(b). For comparison, an exact numerical density matrix simulation of the PASADENA lineshape is presented in Figure 6(d). Excellent

Figure 6 The first experimental demonstration of the PASADENA effect. (a) ^1H NMR spectrum prior to the reaction. The intense lines are due to the acrylonitrile substrate. (b) Signal acquired using a $\pi/4$ pulse immediately following a 1s burst of 50% $p\text{-H}_2$ gas through the solution. (c) Spectrum of the equilibrated sample (following complete spin-lattice relaxation) shows that the signal in (b) was a large transient enhancement. (d) Numerical density matrix simulation demonstrating the agreement of theory with the spectrum in (b)

agreement between the simulation and experiment is evident. The spectrum acquired immediately following the hydrogen burst exhibits antiphase multiplet signals corresponding to the NMR shifts of the conventional quartet and triplet multiplets of propionitrile (centered near 1.7 and 0.6 ppm). After waiting several minutes, the spectrum of Figure 6(d) was acquired. Here, the enhanced transitions observed in Figure 6(b) are totally absent. Spin lattice relaxation has returned the nuclear magnetization to its thermal equilibrium value.

5.2.2 PASADENA Signal Enhancement of $\text{Rh(I)(PPh)}_3\text{H}_2\text{Cl}$

The reaction of H_2 with $\text{Rh(PPh)}_3\text{Cl}$ in the absence of substrate yields $\text{Rh(PPh)}_3\text{ClH}_2$.²⁹ The proton spectrum of the dihydride in the hydride region immediately following reaction with $p\text{-H}_2$ is shown in Figure 8. The multiplet patterns due to both hydride protons are observed; the shift at the position trans to PPh_3 is $\delta_1 = -9.4$ ppm with $J_{\text{PH}} = 160$ Hz, and the second appears at $\delta_2 = -16.8$ ppm with an unresolved spin coupling. The multiplet patterns here exhibit the E/A antiphase pattern rather than A/E as was observed in the PASADENA

Figure 7 In-situ PASADENA hydrogenation apparatus. The volume above the liquid sample can be pressurized to 1.5–2 atm with gas enriched to $\chi_p = 0.5$, while a needle valve on the 1/8" diameter kel-FTM tubing at the gas outlet is adjusted to obtain fine bubbles from a submerged glass capillary tube. The solenoid valves are under pulse-programmer control. The column containing Apachi²¹ (the ortho-para conversion catalyst) consists of a ~ 15 turn, 8 mm inner diameter pyrex coil. Two separate TTL control lines from the pulse programmer were used to control the solenoid valves. This arrangement has the advantage of allowing the gas pressure on the inlet and outlet of the NMR tube to be rapidly equalized following an H_2 burst. To minimize ortho-para reconversion that may occur in the room temperature components of the gas delivery system, valves with Teflon internal surfaces were employed, and all fittings, tubing and connectors were glass, Teflon or kel-FTM

Figure 8 PASADENA enhanced ^1H NMR spectrum (200 MHz) of the hydride region of $\text{RhCl(PPh)}_3\text{H}_2$ formed from the reaction of Wilkinson's catalyst with 50% $p\text{-H}_2$ in deuteriobenzene solution. Due to ligand exchange, the only resolved J splitting is for the hydride proton trans to phosphorous. The E/A multiplet intensity pattern indicates that the unresolved scalar coupling between the hydride protons is negative

spectrum of ethylbenzene or propionitrile. This highlights a unique aspect of the PASADENA experiment. There is usually no information on the sign of J in the weak coupling multiplet pattern, but the PASADENA enhanced multiplet reflects the absolute sign of J . This is immediately evident from the density operator calculations of equation (38) or (26), or by considering the transition intensity pattern predicted by the

two-spin energy level diagram in Figure 2. Secondly, J_{HH} between the hydride protons is not fully resolved, resulting in destructive interference and cancellation of signal amplitude. The apparent low enhancement is also due to the relatively rapid spin-relaxation of the hydride protons. The spin-lattice relaxation time of Zeeman order (T_{1z}) of the dihydride was measured to be 0.28 s.

5.2.3 Stopped-Flow Kinetics of Styrene Hydrogenation by $Rh(I)(PPh_3)_3Cl$

The kinetics and mechanism of Wilkinson's catalyst,²⁶ $Rh(I)(PPh_3)_3Cl$, structure I in scheme 1, has been extensively studied since its discovery nearly 30 years ago. The mechanism is complex, with competing pathways involving mononuclear as well as binuclear dihydride complexes, the concentrations of which are highly sensitive to temperature.¹⁶ A key intermediate in the generally accepted *hydride route* mechanism is structure II shown in Scheme 1.^{26–28} Remarkably, direct evidence for the existence of this intermediate was only recently obtained by PASADENA NMR studies.¹⁶

Here, the application of PASADENA NMR to probe the kinetics of styrene hydrogenation by $Rh(I)(PPh_3)_3Cl$, assuming the generally accepted mechanism outlined in Scheme 1, is described.²⁷ The catalyst and substrate were dissolved in d_6 -benzene and placed into a 5 mm NMR tube connected to the p - H_2 delivery system shown in Figure 7. The time dependence of the product molecule PASADENA signal was mapped by incrementing the delay between the 1.0 s p - H_2 burst and the signal acquisition, resulting in the data set shown in Figure 9(a). A simplified kinetic scheme can be constructed to model this data.

The premixed benzene solution containing $Rh(PPh_3)_3Cl$ and styrene consists of three major species in equilibrium, but the catalyst is largely undissociated:²⁷

The equilibrium is upset as H_2 enters the solution, as it may react with any of the three species. It is known, however, that H_2 reacts only slowly with the triphenylphosphine and olefin coordinated complexes.²⁹ The rate of formation of the intermediate, $Rh(PPh_3)_2H_2Cl(styrene)$, is limited only by the PPh_3 dissociation step. At high H_2 concentration (i.e.,

saturation), this reaction step is effectively unimolecular, and we may write

$$\begin{aligned} -d[Rh(PPh_3)_3Cl]/dt &\approx +d[Rh(PPh_3)_2ClH_2(styrene)]/dt \\ &\approx k_F[Rh(PPh_3)_3Cl] \end{aligned} \quad (44)$$

Under these conditions, the primary pathway of the styrene hydrogenation may be reduced to the following two-step process:

The NMR observable in PASADENA kinetics experiments is the total J -order (or ZZ -order) of each species (ZZ_I , ZZ_{II} , ZZ_P). Thus, the correspondence between the chemical kinetics and the PASADENA kinetics may be represented as follows:

$$\begin{aligned} \frac{d}{dt}[II] &= k_F h(t)[I] - k_D[II] \longrightarrow \frac{d}{dt}ZZ_{II} \\ &= k_F h(t)ZZ_I - ZZ_{II}(k_D + 1/T_{1ZZ}^{II}) \end{aligned} \quad (45)$$

The function $h(t)$ is used to account for the transient presence of H_2 in the solution due to the bubbling. For the J -order on the product, P :

$$\frac{d}{dt}[P] = k_D[P] \longrightarrow \frac{d}{dt}ZZ_P = ZZ_{II}k_D - ZZ_P/T_{1ZZ}^P \quad (46)$$

It is possible to analytically solve these equations for ZZ_{II} and ZZ_P in terms of the parameters k_F , k_D , T_{1ZZ}^{II} and T_{1ZZ}^P . Fortunately, several of these parameters can be deduced from independent experiments. Halpern and Wong investigated the kinetics of formation of $Rh(PPh_3)_2ClH_2$ in the absence of any substrate.²⁹ In the presence of excess H_2 , the rate law with no added PPh_3 yields $k_F \approx 0.34 \text{ s}^{-1}$. The spin-lattice of relaxation of J -order on the product can also be measured under equilibrium conditions. This leaves k_D and T_{1ZZ}^{II} to be determined by fitting the model to PASADENA kinetics data. Implementation of this model produced the theoretical fit to the experimental data shown in Figure 9(a),

Scheme 1

Figure 9 Stopped flow PASADENA kinetics of the formation of ethylbenzene by the $\text{RhCl}(\text{PPh}_3)_3$ catalyzed hydrogenation of styrene using 50% $p\text{-H}_2$. (a) PASADENA signal amplitude as a function of time between the hydrogen burst and the $\pi/4$ detection pulse. (b) Concentration time dependence of **II** and the product alkane determined by fitting the solution of equation (46) to the kinetic data. The shaded area indicates the period during which 50% $p\text{-H}_2$ is bubbled through the solution containing the catalyst and substrate

yielding $k_D = 0.160 \text{ s}^{-1}$, $T_{\text{IZZ}}^{\text{II}} = 1.68 \text{ s}$, and $T_{\text{IZZ}}^{\text{P}} = 8.15 \text{ s}$.¹² The rate constants can be inserted into the conventional kinetic expressions to find the concentration time dependence of each species, as shown in Figure 9(b).

5.2.4 Evidence for Catalytic Intermediates from PASADENA NMR

Perhaps the most intriguing aspect of the PASADENA method is the potential to observe catalytic intermediates or other transient species in hydrogenation reactions. For example, Harthun and Bargon reported a transient rhodium-substrate-dihydrido species in the hydrogenation of itaconic acid dimethyl ester by a cationic rhodium complex.³⁰ The hydride region exhibited enhancements that were not observed in the absence of the substrate, but the spectrum could not be unequivocally assigned to a catalytic intermediate since the signals did not appear to be associated with a *cis* arrangement of the H_2 protons as would be expected in a catalytic hydrogenation intermediate.

The occurrence of catalytic intermediates can also be inferred from the appearance of the PASADENA enhanced multiplet patterns. Bargon et al. have noted that enhanced

product spectra resulting from the $p\text{-H}_2$ addition to norbornadiene depended on the catalyst used. This could be explained if the rate of reaction is so rapid that the spin coherences (off-diagonal element of the density operator) are preserved, as described in Section 4.3. The density matrix representing the spin system resulting from the addition of $p\text{-H}_2$ to the catalyst or the product would then consist of a diagonal part, $\hat{I}_{zA}\hat{I}_{zB}$ (J -order) as well as off-diagonal terms associated with zero and double quantum coherence (see equations (35)–(38)). The density operator will reflect the spin Hamiltonian on the intermediate as well as the lifetime of this species, and this technique may therefore be used to differentiate between structural candidates for catalytic intermediates that cannot be directly observed.

5.2.5 Elucidation of a Reaction Pathway Involving a Catalytic Intermediate

Using a similar catalytic rhodium catalyst, $\text{Rh}(\text{diphos})^+$, a new type of transient species was observed in the hydrogenation of styrene.¹² The reaction solutions initially contained 1 ml $\text{d}_6\text{-acetone}$, 0.015 g of the catalyst precursor, $[\text{Rh}(\text{diphos})(\text{nbd})]^+\text{PF}_6^-$, and 0.1 ml styrene in a 5 mm standard NMR tube. The catalyst was activated by bubbling $p\text{-H}_2$ through the solution for several seconds to release norbornane, while in the process yielding dramatic PASADENA NMR enhancement on both the norbornene and norbornane adducts. After about 20 s of H_2 bubbling, these signals subside, and in place of the norbornadiene the styrene becomes coordinated to the $\text{Rh}(\text{diphos})^+$ with an equilibrium constant of $K_2 = 20 \text{ M}^{-1}$.³¹

The accepted mechanism for the $\text{Rh}(\text{diphos})^+$ catalyzed hydrogenation of styrene is presented in Scheme 2.³² The rate-limiting step is the formation of the rhodium-olefin-dihydride species (**III**). PASADENA enhanced NMR studies have revealed a new type of transient species, identified as a rhodium- η_6 -ethylbenzene complex identified as **V** in the scheme. The PASADENA spectrum (Figure 10) exhibits two sets of enhanced ethylbenzene alkyl group resonances. In the first set, the chemical shifts of the CH_3 and CH_2 group protons are the same as that of ethylbenzene in this solvent, and after 30–40 individual 1 s H_2 bursts, thermal equilibrium NMR signals can be detected and continue to grow in intensity as product accumulates. The other pair of enhanced multiplets occurs at lower shielding, but there is no accumulation of a thermally polarized signal at these chemical shifts. These observations lead to the hypothesis that the pair of resonances at higher shielding represent a transient *bound* alkane species, depicted as **V** in scheme 2. The decay rates of each pair of resonances was measured by varying the delay between the H_2 burst and the acquisition pulse. Decay times of 1.94 s and 3.35 s were obtained for the J -order of the bound and free forms of ethylbenzene, respectively. The faster decay of the bound form could be attributed to (1) the shorter rotational correlation time of the bound complex or (2) the dissociation of the bound alkane to yield free alkane.

The proposed bound $\rightarrow$ free pathway was investigated by 2D PASADENA exchange NMR.¹² Recall that cross-peaks in a 2D exchange experiment can confirm or refute the existence of an exchange event, and when cross peak/diagonal peak ratios can be measured from a series of 2D spectra in which the

Scheme 2

exchange time is varied, the exchange rate can be determined. Section 5.2.6 describes the details of the pulse sequence development used in this investigation.

5.2.6 Two-Dimensional Exchange PASADENA NMR

This section describes some of the considerations for designing a pulse sequence for probing reaction pathways using 2D exchange PASADENA NMR. The sequence shown below was developed to investigate the rate of release of the bound form of ethylbenzene from Rh[diphos]⁺ as described in Section 5.2.5.

The reaction is initiated with a burst of p -H₂ followed by a delay to allow the solution to settle. Pure zero quantum coherence (ZQC) is generated in the preparation period by a $\pi/2$ pulse followed by 3 periods during which a homospoil gradient is applied. The choice of ZQC has the advantage that evolution of ZQC is independent of the receiver offset. This makes the sequence more robust and eases the task of setting the preparation time τ . Conversion into single quantum coherence is optimized by a second $\pi/2$ pulse. One only needs to consider the evolution of single quantum coherence during t_1 since the 1Q $\rightarrow$ 1Q coherence transfer echo filter removes all other coherence orders. Following the evolution of 1Q coherence during t_1 , the coherence is stored as a superposition of Zeeman and J -order populations using a pulse θ_3 . During the mixing period, τ_m , chemical exchange or cross-relaxation is allowed to occur. The populations are subsequently transformed back to single quantum coherences for detection with the pulse θ_4 .

A two-spin product operator calculation reveals how the choice of the pulse angles θ_3 and θ_4 affects the type of spin order that is stored and the factors that impact the efficiency of its detection. The density operator following preparation, evolution, and storage is:

$$\begin{aligned} \hat{\rho}(\tau, t_1, \tau_1) = & \frac{1}{2} \hat{I}_{z1} \sin \theta_3 \sin(\Delta\omega_z \tau) \sin\left(\frac{J}{2} t_1'\right) \\ & \times \{\sin \delta(\vec{r}) \tau_1 \sin \omega_{z1} t_1' - \cos \delta(\vec{r}) \tau_1 \cos \omega_{z1} t_1'\} \\ & - \frac{1}{2} \hat{I}_{z2} \sin \theta_3 \sin(\Delta\omega_z \tau) \sin\left(\frac{J}{2} t_1'\right) \\ & \times \{\sin \delta(\vec{r}) \tau_1 \sin \omega_{z2} t_1' - \cos \delta(\vec{r}) \tau_1 \cos \omega_{z2} t_1'\} \\ & + \hat{I}_{z1} \hat{I}_{z2} \sin(\Delta\omega_z \tau) \sin \theta_3 \cos \theta_3 \cos\left(\frac{J}{2} t_1'\right) \\ & \times \{\sin \delta(\vec{r}) \tau_1 [\cos \omega_{z2} t_1' - \cos \omega_{z1} t_1'] \\ & + \cos \delta(\vec{r}) \tau_1 [\sin \omega_{z2} t_1' - \sin \omega_{z1} t_1']\} \end{aligned} \quad (47)$$

where $t_1' = t_1 + \tau_1$, $\delta(\vec{r})$ is the offset due to the homospoil gradient, and $\Delta\omega_z$ is the chemical shift difference. This expression is written in a form to emphasize that the population differences stored during the exchange time can be written as a linear combination of Zeeman and J -order, the weight of each type being dependent on the pulse angle θ_3 . J -order is fully suppressed using $\theta_3 = \pi/2$, while Zeeman order is optimized. Also note that the t_1 dependence of the Zeeman order contains the factor $\sin J^b t_1'/2$ responsible for the A/E multiplet pattern in the frequency domain. Additional insights can be gained by following through with the signal calculation. The 2D time-domain signal associated with the cross-peak due to slow bound $\rightarrow$ free exchange is:

$$S_{b \rightarrow f} = \frac{1}{4} \sin(\Delta_{1,2}^{b,b} \tau) \cos\left(\frac{J^b}{2} t'_1\right) \sin\left(\frac{J^f}{2} t'_2\right) \sin \theta_3 \cos \theta_3 \sin \theta_4 \cos \theta_4 \\ \times \left\{ \exp\left[-i\left(\Delta_{1,1}^{b,f} \tau_1 + \omega_{z1}^b t_1 - \omega_{z1}^f t_2\right)\right] \right.$$

Figure 10 200 MHz PASADENA enhanced ^1H NMR spectrum of ethylbenzene formed by the $\text{Rh}(\text{diphos})^+$ catalyzed hydrogenation of styrene in d_6 -acetone solvent. The appearance of two pairs of methyl and methylene multiplets indicates that two distinct alkane species are formed in approximately equal amounts. The multiplets centered at 2.7 and 1.25 ppm occur at the same chemical shifts as free ethylbenzene, while the peaks marked by asterisks are attributed to an intermediate in a parallel pathway in which the nascent alkane remains or becomes bound to the Rh complex. (b) 200 MHz PASADENA 2D exchange spectrum (magnitude shown) resulting from the sequence described in the text, with $\tau_m = 2.0$ s, a 2 s 50% $p\text{-H}_2$ burst, and $\theta_3 = \theta_4 = \pi/2$. Single quantum transitions of the methyl region of ethylbenzene are shown in both frequency dimensions. An off-diagonal cross-peak due to the release of the bound alkane from the catalyst during τ_m would be observed in the region indicated by the white circle if the alkane which was “bound” prior to the first pulse of the sequence were to become free during τ_m . The diagonal multiplets centered at 0.96 and 1.25 ppm represent ethylbenzene that remained in the bound and free chemical environments throughout the entire sequence

$$\begin{aligned}
 & -\exp\left[-i\left(\Delta_{2,1}^{b,f}\tau_1 + \omega_{z2}^b t_1 - \omega_{z1}^f t_2\right)\right] \\
 & +\exp\left[-i\left(\Delta_{1,2}^{b,f}\tau_1 + \omega_{z1}^b t_1 - \omega_{z2}^f t_2\right)\right] \\
 & -\exp\left[-i\left(\Delta_{2,2}^{b,f}\tau_1 + \omega_{z2}^b t_1 - \omega_{z2}^f t_2\right)\right] \\
 & +\frac{1}{4}\sin\left(\Delta_{1,2}^{b,b}\tau\right)\sin\theta_3\sin\theta_4\sin\left(\frac{J^b}{2}t_1'\right)\cos\left(\frac{J^f}{2}t_2'\right) \\
 & \times\left\{\exp\left[-i\left(\omega_{z2}^b t_1 - \omega_{z2}^f t_2\right)\right] - \exp\left[-i\left(\omega_{z1}^b t_1 - \omega_{z1}^f t_2\right)\right]\right\} \quad (48)
 \end{aligned}$$

where $\Delta_{i,j}^{x,y} = \omega_{zi}^x - \omega_{zj}^y$ and $t_2' = t_2 + \tau_1$. The diagonal bound peak signals can be derived from this expression by setting $\omega_{zi}^f \rightarrow \omega_{zi}^b$ and similarly for the “f” diagonal peaks we set $\omega_{zi}^b \rightarrow \omega_{zi}^f$. Inspection of this time-domain cross-peak signal reveals that the first term, which is optimized for the choice $\theta_3 = \theta_4 = 45^\circ$, produces an antiphase (A/E) doublet in the ω_2 domain while yielding an absorption phase doublet in ω_1 . This is significant because it implies that the spectrum of the bound species can be indirectly observed with undiminished PASADENA enhancement even if $J^b = 0$ so long as $|J^f| \gg 1/T_2^f$. Conversely, the choice $\theta_3 = \theta_4 = 90^\circ$ will facilitate the observation of the fully enhanced transitions on the free species even if the J -coupling on this species was unresolved.

Now consider the application of the 2D exchange PASADENA NMR sequence to the particular example described in Section 5.2.5 in which two sets of enhanced ethylbenzene resonances were detected. Recall that one of these sets corresponded to ethylbenzene bound to $\text{Rh}[\text{diphos}]^+$, while the other represented free ethylbenzene. For the resolved couplings of bound and free ethylbenzene, where $J^b = J^f$, PASADENA enhanced signals are observed regardless of the choice of θ_3 and θ_4 . Yet there is a potential advantage to the choice $\theta_3 = \theta_4 = 45^\circ$ if there is a loss of catalytic activity during the course of the hydrogenation reaction. The finite lifetime of the catalyst may possibly limit the number of t_1 points that can be collected before the reaction terminates, which in turn limits the resolution of the J -coupling in this dimension.

Under the conditions used to study the $\text{Rh}[\text{diphos}]^+$ catalyzed hydrogenation of styrene, approximately 256 t_1 points could be acquired before the enhanced signal disappeared. The 2D exchange PASADENA NMR spectrum of the methyl region is presented in Figure 10b. A density matrix simulation of the zero quantum coherence formed by a $\pi/2$ pulse in the five spin system was used to choose the optimum preparation time of 409 ms. The spectrum was acquired using $\tau_w = 2$ s, $\theta_3 = \theta_4 = 90^\circ$, and $\tau_m = 2$ s. In the case of the proposed bound $\rightarrow$ free pathway, cross-peaks are not observed in the 2D PASADENA exchange spectrum. However, from the S/N ratio of the diagonal peak magnitude signal, an upper limit of $k_6 \leq 0.05 \text{ s}^{-1}$ for the bound $\rightarrow$ free step can be established. Thus, it is concluded that this pathway is not involved in the primary catalytic hydrogenation cycle.

6 THE ALTADENA EFFECT

Recall that in the PASADENA effect the population distribution of the high field eigenstates was determined by the transition probabilities that may be calculated from projection of the singlet state (in the case of $p\text{-H}_2$) onto the high field eigenstates of the product molecule. This procedure relies on the validity of the sudden approximation in which the spin Hamiltonian was assumed to change instantaneously due to the rapid chemical addition to a substrate. Subsequent to product formation, there was no further change in the internal Hamiltonian before detection of the spin order by NMR.

Now consider a variation of the PASADENA effect whereby the hydrogenation product is formed at essentially zero magnetic field and then adiabatically transported to high magnetic field for NMR acquisition. Using the $\text{Rh}(\text{PPh}_3)_3\text{Cl}$

catalyzed hydrogenation of styrene, Weitekamp and Pravica³³ demonstrated that this procedure results in an initial spin state distribution that is qualitatively different from that obtained by doing the hydrogenation entirely at high field, as in PASADENA. Because the enhanced NMR spectra that result from this field cycled procedure exhibit net alignment of the multiplets, the technique was given the acronym ALTADENA (Adiabatic Longitudinal Transport After Dissociation Engenders Net Alignment). Here, the theoretical description presented in the original paper is outlined.³³

Upon reaction at zero field, the rotational energy splitting suddenly becomes negligible, but the singlet-triplet spin eigenstates remain the same. As the product molecule is adiabatically transported to high magnetic field, the eigenstates develop into the direct product states of the weakly coupled system. As illustrated in Figure 11, these state-to-state correlations, assuming J and $\Delta\omega_z$ have the same sign, are as follows: $|\alpha\alpha\rangle \rightarrow |\alpha\alpha\rangle$, $2^{-1/2}(|\alpha\beta\rangle + |\beta\alpha\rangle) \rightarrow |\alpha\beta\rangle$, $2^{-1/2}(-|\alpha\beta\rangle + |\beta\alpha\rangle) \rightarrow |\beta\alpha\rangle$, and $|\beta\beta\rangle \rightarrow |\beta\beta\rangle$. The high field population distribution resulting from adiabatic transport is not the same as the distribution obtained under the sudden approximation (compare to Figure 2).

Using a procedure analogous to the one used to find the density operator of H_2 , the density operator corresponding to the population distribution due to hydrogenation and transport to high field is

$$\hat{\rho}_{ad} = \frac{1}{4} - f \left[\hat{I}_{z1} \hat{I}_{z2} \pm \frac{1}{2} (\hat{I}_{z1} - \hat{I}_{z2}) \right] \quad (49)$$

Of course, when J and $\Delta\omega_z$ have opposite signs, the correlation of the singlet state is to the $|\alpha\beta\rangle$ state rather than to the $|\beta\alpha\rangle$ and the lower (−) sign in equation (49) applies. It is evident from equation (49) that the NMR signal will be a superposition of contributions from both terms in square brackets, with the relative contribution determined by the applied pulse angle. As was shown in Section 3.4 the J -order term $\hat{I}_{z1} \hat{I}_{z2}$ yields a spectrum that is optimized for a $\theta = \pi/4$ pulse and consists of a A/E doublet at each chemical shift. The term $\hat{I}_{z1} - \hat{I}_{z2}$ yields *net alignment* of each multiplet with the relative amplitudes determined by the usual Pascal's triangle

Figure 11 Energy level correlation diagram in the ALTADENA experiment

factors. The signal intensity from this term is optimized with $\theta = \pi/2$. A signal calculation yields the following relative transition amplitudes:

$$\begin{aligned} (f/2) \sin \theta (1 + \cos \theta) : (f/2) \sin \theta (1 - \cos \theta) \\ -(f/2) \sin \theta (1 - \cos \theta) : -(f/2) \sin \theta (1 + \cos \theta) \end{aligned} \quad (50)$$

Consequently, only two transitions are observed when the signal is detected with a small pulse angle. This is consistent with the expectations of the population distribution shown in Figure 11. A $\pi/2$ detection pulse elicits two doublets with relative amplitudes of $\{1:1\}$ and $\{-1:-1\}$.

The ALTADENA effect was originally demonstrated by Pravica and Weitekamp in the $Rh(I)[PPh_3]_3Cl$ catalyzed hydrogenation of styrene by bubbling 50% p - H_2 for 1s at a field of 9 mT followed by insertion of the sample into the NMR spectrometer at a field of 4.7 T.³³ The transport step was carried out in less than about 3 s. The spectrum resulting from a small tip angle pulse ($\pi/11$ rad) is shown in Figure 12(a), and the spectrum resulting from a $\pi/2$ pulse is shown in Figure 12(b). The amplitude patterns are in agreement with the predictions of theory if the density operator given in equation (49) is generalized to 5 spins:

$$\hat{\rho}_{ad} = -f \left[\hat{I}_{za} \hat{I}_{zb} \pm \frac{1}{2} (\hat{I}_{za} - \hat{I}_{zb}) \right] \quad (51)$$

Here, the subscripts “a” and “b” refer to the magnetically equivalent CH_3 and CH_2 protons of ethylbenzene. The signal calculation yields the following relative line amplitudes:

For the quartet:

$$\begin{aligned} \{\sin \theta (1 + \cos \theta)/2 : \sin \theta (3 + \cos \theta)/2 : \\ \sin \theta (3 - \cos \theta)/2 : \sin \theta (1 - \cos \theta)/2\} \end{aligned} \quad (52)$$

Figure 12 Experimental ALTADENA experiment (courtesy of Weitekamp and Pravica)

For the triplet:

$$\{-\sin\theta(\cos\theta - 1) : -2\sin\theta : -\sin\theta(1 + \cos\theta)\} \quad (53)$$

By analogy with the 2-spin case, a $\pi/2$ pulse yields net alignment with relative amplitudes determined by the usual Pascal's triangle factors, while a small angle pulse leads to the ratios $\{1:2:1:0\}$ and $\{0:-2:-2\}$ in which transitions are noticeably absent from each multiplet. In conclusion, the predictions of the density operator theory for the ALTADENA effect are in striking agreement with experiment.

7 THEORY OF ORTHO/PARA D₂ ENHANCEMENT

7.1 Nuclear Spin Functions of D₂

As with H₂, the product of the rotational and nuclear spin symmetries must be correlated, but due to the fact that deuterons are bosons ($I = 1$), odd j rotational states are associated with antisymmetric (para) spin states, while even valued j correspond to symmetric (ortho) spin states. Therefore, the ground rotational state is o -D₂. Here, the derivation of the density operator in the case of molecular addition of D₂ with arbitrary ortho/para composition will be presented.^{12,37} The time-averaged operator required to calculate the PASADENA signal in the slow-reaction rate limit will be obtained from this result.

There are $2I + 1 = 3$ states $|m_i\rangle$ of a deuterium nuclear spin, which shall be labeled $|1\rangle$, $|0\rangle$, $|-1\rangle$. For a deuteron pair, there are $(2I + 1)^2 = 9$ direct product states $|m_1 m_2\rangle$. These are eigenfunctions of $\hat{I}_z = \hat{I}_{z1} + \hat{I}_{z2}$, but not of $\hat{I}^2 = (\hat{I}_1 + \hat{I}_2)^2$. Since angular momentum must be conserved in an isolated molecule, the total angular momentum is a quantum mechanical constant of the motion, and hence $[\hat{\mathcal{H}}, \hat{I}^2] = 0$. It follows that $\hat{\mathcal{H}}$ and $\hat{I}^2$ have the same spin eigenstates. The eigenstates of $\hat{I}^2$ can be obtained from the appropriate unitary transformation of the direct product states, $|m_1 m_2\rangle$. The appropriate linear combination can be found by evaluating the Clebsch–Gordon coefficients:^{34–36}

$$C_{m_1 m_2 m}^{I_1 I_2 I} \equiv \langle I_1 m_1 I_2 m_2 | I_1 I_2 I m \rangle \quad (54)$$

In terms of these coefficients, the coupled states are given by

$$|I_1 I_2 I m\rangle = \sum_{m_1 m_2} C_{m_1 m_2 m}^{I_1 I_2 I} |I_1 m_1 I_2 m_2\rangle \quad (55)$$

where the resultant values of I are given by the Clebsch–Gordon series; $I = \{I_1 + I_2, \dots, |I_1 - I_2|\}$. For D₂, $I_1 = I_2 = 1$, and $I = \{2, 1, 0\}$. This yields three manifolds consisting of 5, 3 and 1 state(s), respectively. The eigenstates of $\hat{I}^2$ are as follows:

$$\text{ortho-D}_2 \begin{cases} |22\rangle = |\alpha\alpha\rangle \\ |21\rangle = 2^{-1/2}(|\alpha 0\rangle + |0\alpha\rangle) \\ |20\rangle = 6^{-1/2}(|\alpha\beta\rangle + 2|00\rangle + |\beta\alpha\rangle) \\ |2-1\rangle = 2^{-1/2}(|\beta 0\rangle + |0\beta\rangle) \\ |2-2\rangle = |\beta\beta\rangle \\ |00\rangle = 3^{-1/2}(|\alpha\beta\rangle - |00\rangle + |\beta\alpha\rangle) \end{cases} \quad (56)$$

$$\text{para-D}_2 \begin{cases} |11\rangle = 2^{-1/2}(|0\alpha\rangle - |\alpha 0\rangle) \\ |10\rangle = 2^{-1/2}(|\beta\alpha\rangle - |\alpha\beta\rangle) \\ |1-1\rangle = 2^{-1/2}(|\beta 0\rangle - |0\beta\rangle) \end{cases} \quad (57)$$

The transformation matrix formed by these eigenvectors can be used to diagonalize the Hamiltonian. The transformation is represented as

$$\{\hat{\mathcal{H}}\}_{\text{Eigen}} = A\{\hat{\mathcal{H}}\}_{\text{prod}}A^T \quad (58)$$

7.2 Molecular Deuterium Nuclear Spin Density Matrix

The density matrix for some arbitrary mixture of ortho/para deuterium may be written as

$$\rho = \begin{pmatrix} \chi_o/6 & & & & & & & & \\ & \chi_o/6 & & & & & & & \\ & & \chi_o/6 & & & & & & \\ & & & \chi_o/6 & & & & & \\ & & & & \chi_o/6 & & & & \\ & & & & & \chi_p/3 & & & \\ & & & & & & \chi_p/3 & & \\ & & & & & & & \chi_p/3 & \\ & & & & & & & & \chi_p/3 \end{pmatrix} \quad (59)$$

While it is most convenient to specify the matrix elements in the eigenbasis, the calculations that follow are more easily carried out in the direct product basis. The required transformation of the density matrix is:

$$\{\hat{\mathcal{H}}\}_{\text{prod}} = A^T \{\hat{\mathcal{H}}\}_{\text{Eigen}} A \quad (60)$$

With the density matrix now in the direct product basis, it may be expressed as a linear combination of spin operators. In the case of H₂, this was $\hat{I}/4 - f\hat{I}_1 \cdot \hat{I}_2$. This operator is a scalar, i.e., it commutes with $\hat{I}$. Similarly, the density operator of D₂ should also be of a scalar form. The construction of scalar operators is achieved using irreducible tensor operators. The irreducible tensor operator (ITO) of rank k is defined as the set of $2k + 1$ operators T_q^k that transform under coordinate rotations according to the relation^{34–36}

$$D(\alpha, \beta, \gamma) T_q^k D^{-1}(\alpha, \beta, \gamma) = \sum_{q'} T_{q'}^k \mathcal{D}_{q'q}^{(k)}(\alpha, \beta, \gamma) \quad (61)$$

where q and q' take on integer values running from $-k$ to $+k$ and $\mathcal{D}_{q'q}^{(k)}(\alpha, \beta, \gamma)$ are elements of the Wigner rotation matrix. To form the density operator of D₂, compound irreducible tensor operators are employed. The general expression for a compound irreducible tensor operator is³⁴

$$\{T^{k_1}(1) \otimes T^{k_2}(2)\}_q^k = \sum_{q_1 q_2} \langle k_1 q_1 k_2 q_2 | k_1 k_2 k q \rangle T_{q_1}^{k_1}(1) T_{q_2}^{k_2}(2) \quad (62)$$

The coefficients in the summation are the Clebsch–Gordon coefficients. Since the D₂ density operator is expected to be a scalar, only the $k = q = 0$ compound ITO needs to be evaluated. In terms of the 3- j symbol,

$$\{T^{k_1}(1) \otimes T^{k_2}(2)\}_0^0 = \sum_{q_1 q_2} (-1)^{k_1 - k_2} \begin{pmatrix} k_1 & k_2 & 0 \\ q_1 & -q_2 & 0 \end{pmatrix} \times T_{q_1}^{k_1}(1) T_{q_2}^{k_2}(2) \quad (63)$$

where

$$\begin{pmatrix} k_1 & k_2 & 0 \\ q_1 & -q_2 & 0 \end{pmatrix} = (-1)^{k_1 - m_1} (2k_1 + 1)^{-1/2} \delta_{k_1 k_2} \delta_{m_1 m_2} \quad (64)$$

The functional form requires that the rank of the individual tensors be the same (i.e., $k' = k_1 = k_2$). The resulting zero rank compound ITO becomes

$$\begin{aligned} \{T^k(1) \otimes T^k(2)\}_0^0 &= \sum_q (-1)^{k-q} (2k' + 1)^{-1/2} T_q^k(1) T_{-q}^k(2) \\ &= (-1)^k (2k + 1)^{-1/2} \mathcal{A}^k \end{aligned} \quad (65)$$

where
$$\mathcal{A}^k = \sum_q (-1)^q T_q^k(1) T_{-q}^k(2) \quad (66)$$

Assume that the density operator can be decomposed as follows:

$$\begin{aligned} \hat{\rho} &= c_0 \mathcal{A}_0 + c_1 \mathcal{A}_1 + c_2 \mathcal{A}_2 \\ &= c_0 T_0^0(1) T_0^0(2) + c_1 [T_0^1(1) T_0^1(2) - T_{-1}^1(1) T_1^1(2) - T_1^1(1) T_{-1}^1(2)] \\ &\quad + c_2 [T_0^2(1) T_0^2(2) - T_{-1}^2(1) T_1^2(2) - T_1^2(1) T_{-1}^2(2) \\ &\quad + T_{-2}^2(1) T_2^2(2) + T_2^2(1) T_{-2}^2(2)] \end{aligned} \quad (67)$$

In terms of the Cartesian spin operators,

$$\begin{aligned} \hat{\rho} &= c_0 \hat{1} + c_1 \hat{I}_1 \cdot \hat{I}_2 \\ &\quad + \frac{c_2}{4} \left\{ \frac{8}{3} \hat{1} + \hat{I}_{-1}^2 \hat{I}_{+2}^2 + \hat{I}_1^2 \hat{I}_{-2}^2 + 6 \hat{I}_{z1}^2 \hat{I}_{z2}^2 - 4 \hat{I}_{z1}^2 - 4 \hat{I}_{z2}^2 \right. \\ &\quad + (\hat{I}_{-1} \hat{I}_{+2} + \hat{I}_{+1} \hat{I}_{-2}) (4 \hat{I}_{z1} \hat{I}_{z2} - \hat{1}) \\ &\quad \left. + 2(\hat{I}_{-1} \hat{I}_{+2} - \hat{I}_{+1} \hat{I}_{-2}) (\hat{I}_{z1} - \hat{I}_{z2}) \right\} \end{aligned} \quad (68)$$

The next step is to find the matrix representation of ρ so that it may be equated with the D₂ density matrix and the coefficients c_0 , c_1 and c_2 determined. Equating the elements of the two different matrix formulations of ρ ,

$$c_0 = \frac{1}{9} \quad c_1 = \frac{f}{2} \quad c_2 = f \quad (69)$$

where f is related to the mole fraction of p -D₂ by $f = (1/3 - \chi_p)/4$. Equation (68), along with the coefficients given in equation (69), is in agreement with expressions derived by Pravica.³⁷

7.3 The Time-Averaged Initial Condition

When the D₂ addition rate is slow compared with the period of the ensuing coherence evolution, the off-diagonal elements of the density matrix (expressed in the eigenbasis of the adduct spin Hamiltonian) vanish and the time averaged density matrix becomes diagonal. The signal arising from this averaged initial condition will now be calculated, assuming the weak-coupling limit as the case may be in liquids. Dropping the off-diagonal terms,

$$\begin{aligned} \hat{\rho}_{\text{diag}} &= \sum_i \langle i | \rho | i \rangle | i \rangle \langle i | \\ &= \frac{1}{9} \hat{1} + \frac{f}{2} (\hat{I}_{z1} \hat{I}_{z2} + 3 \hat{I}_{z1}^2 \hat{I}_{z2}^2 - 2 \hat{I}_{z1}^2 - 2 \hat{I}_{z2}^2) \end{aligned} \quad (70)$$

The single-quantum operators generated from the response of $\hat{\rho}_{\text{diag}}$ to a θ_x rf pulse are:

$$\begin{aligned} \hat{\rho}_{\text{diag}} &\xrightarrow{\theta \hat{I}_x} \frac{-f}{2} \sin \theta \cos \theta \{ \hat{I}_{y1} \hat{I}_{z2} + \hat{I}_{z1} \hat{I}_{y2} \\ &\quad - 2(\hat{I}_{y1} \hat{I}_{z1} + \hat{I}_{z1} \hat{I}_{y1} + \hat{I}_{y2} \hat{I}_{z2} + \hat{I}_{z2} \hat{I}_{y2}) \\ &\quad - 3 \cos^2 \theta (\hat{I}_{y1} \hat{I}_{z1} \hat{I}_{z2}^2 + \hat{I}_{z1} \hat{I}_{y1} \hat{I}_{z2}^2 \\ &\quad + \hat{I}_{z1}^2 \hat{I}_{y2} \hat{I}_{z2} + \hat{I}_{z1}^2 \hat{I}_{z2} \hat{I}_{y2}) \} \end{aligned} \quad (71)$$

The FID arises from terms which evolve under $\hat{\mathcal{H}}_{\text{int}}$ to yield nonzero traces with $\hat{I}_+$. The relevant traces are

$$\begin{aligned} \text{Tr}\{\hat{I}_+ \hat{I}_{x1} \hat{I}_{z2}^2\} &= \text{Tr}\{\hat{I}_+ \hat{I}_{z1}^2 \hat{I}_{x2}\} = 4 \\ \text{Tr}\{\hat{I}_+ \hat{I}_{y1} \hat{I}_{z2}^2\} &= \text{Tr}\{\hat{I}_+ \hat{I}_{z1}^2 \hat{I}_{y2}\} = 4i \end{aligned} \quad (72)$$

After expanding the trigonometric functions of the $I = 1$ spin operators:

$$S(t) = 2f \sin \theta \cos \theta \sin Jt \{ e^{-i\omega_{z1}t} + e^{-i\omega_{z2}t} \} \quad (73)$$

This signal closely resembles the PASADENA signal for a two-spin system of weakly coupled protons with the exception that the splitting between the two lines is now $2J$. Again, maximum signal is obtained using a $\theta = \pi/4$ pulse, and the central transition is again absent in the PASADENA spectrum in which the absolute line amplitudes are $\{-1/12, 0, +1/12\}$ for pure p -D₂. The signal amplitudes derived from equation (73) may be compared to the conventional signal derived from Zeeman order in the high temperature regime.

$$\hat{\rho}(0) = b(T) \hat{I}_z \xrightarrow{\frac{\pi}{2} \hat{I}_y} \xrightarrow{\hat{\mathcal{H}}_{\text{int}}} \hat{\rho}(t)$$

$$S(t) = \text{Tr}\{\hat{I}_+ \hat{\rho}(t)\} = 2b(T)(1 + 2 \cos Jt) \{ e^{-i\omega_{z1}t} + e^{-i\omega_{z2}t} \} \quad (74)$$

Here, the spectrum of two weakly coupled deuterons exhibits two triplets with line amplitudes $2b(T)\{1, 1, 1\}$.

8 PASADENA EFFECT AT A SOLID SURFACE

This section reviews the extension of the PASADENA effect to H₂ chemisorption at the surface of ZnO.³⁸ Adsorption, kinetics and infrared studies have previously characterized the active sites of the catalytic surface.³⁹⁻⁴¹ Due to the appearance of O-H and Zn-H adsorption bands in the infrared spectra,⁴² it has been proposed that the following surface species is produced upon chemisorption:

Molecular addition is a fundamental requirement to observe the PASADENA effect since randomization of the spins on

a surface would lead to immediate loss of spin order. In ZnO, isotopes studies have shown that a mixture of H₂ and D₂ added to the surface simultaneously during olefin hydrogenation yields predominantly alkane-d₂ and alkane-H₂ adducts. This is evidence that the two protons of H₂ remain in close proximity once adsorbed to the active site. Therefore, a PASADENA signal enhancement is expected at these sites, while in principle, physisorbed or binding sites that dissociate hydrogen should be discriminated against.

Adsorption experiments on powdered ZnO⁴³ were performed using both normal H₂ and para-enriched H₂ at room temperature and under moderate vacuum conditions. A 0.3 g sample of ZnO was packed into a modified NMR tube connected to an evacuation line and a *p*-H₂ delivery line with a standing pressure of 160 kPa and held in place by glass wool. The sample was first heated under vacuum to 673–723 K for >4 h. Parahydrogen was prepared by passing H₂ gas through activated Apachi²¹ at 77 K. NMR was performed at 4.7 T (1H resonance at 198 MHz). For each spectrum a period of evacuation of the sample, typically several minutes, was followed by a brief burst of *p*-H₂, and then immediate re-evacuation. A resonant rf pulse (1.8 μs, 45° flip angle) to excite coherence was delivered at the end of the nominal burst time, followed by detection of transverse magnetization (128 points at 10 ms/point after 20 ms delay). The transients were zero-filled to 256 points before Fourier transformation without apodization. Figure 13(a) shows the spectrum obtained when a ~50 ms burst of *n*-H₂ was delivered to the sample. The broad, weak resonance is due to species present before the burst. The relatively sharp (FWHM = 1 kHz) resonance was attributed to gas-phase *o*-H₂ (*p*-H₂ has no NMR signal). Figure 13(b) shows the spectrum obtained after the same procedure was repeated using para-enriched H₂. The prominent anti-phase signal is interpreted as the PASADENA NMR of hydrogen chemisorbed on ZnO. This PASADENA enhanced signal is unlike the NMR lineshape obtained with *n*-H₂ here or in previous NMR studies of H₂ on ZnO.^{44,45} Figure 13(c) presents

Figure 13 (a) ¹H NMR spectrum immediately after a ~50 ms burst of *n*-H₂ delivered to polycrystalline ZnO. (b) Spectrum recorded under the same conditions as in (a) but using 50% *p*-H₂. (c) Pure PASADENA spectrum obtained by taking the ortho-weighted difference of (a) and (b) as described in the text

the pure PASADENA NMR spectrum after subtraction of the broad background signal. The resonance due to gaseous *o*-H₂ in the *n*-H₂ experiment has also been subtracted away after scaling by a factor of 2/3 to account for the ratio of the mole fraction of *o*-H₂ in each experiment. Larger signal amplitudes were observed with burst lengths of 100 and 200 ms, indicating that additional binding sites are available for chemisorption. However, the line shapes (not shown) also changed with increasing exposure to *p*-H₂. This could be either due to adsorption by different types of binding sites or due to spin-diffusion to other protons in the vicinity of the binding site. The signal enhancement in these spectra was estimated to be in the neighborhood of 400–1000.

When ZnO is continuously exposed to *p*-H₂, the enhancement disappears over a period of tens of seconds, indicating that the adsorption sites observed by PASADENA become saturated. As the adsorption sites become occupied, the signal due to chemisorbed H₂ dies off due to spin lattice relaxation. However, the PASADENA signal following a short burst of *p*-H₂ was consistent and repeatable if the sample was evacuated for a few seconds in between bursts. These experiments indicate reversible binding sites consistent with Type I adsorption at room temperature.

The PASADENA line shape contains information about the electronic structure of the catalytically active sites of ZnO. It can be quantitatively modeled if it is assumed that (1) the line shape obtained for a short (50 ms) *p*-H₂ burst arises from a single type of adsorption site and (2) that the product state is taken to be a static, magnetically isolated two-spin system formed by dissociative chemisorption. The high-field, rotating frame spin Hamiltonian including chemical shifts, dipolar and scalar couplings is given by equation (9). Since the ZnO is in a high surface area, polycrystalline form, the simulation of the spectrum must account for all random distribution of orientations of the binding site with respect to the magnetic field. The anisotropy of the dipolar and chemical shielding interactions can be expressed in terms of the principal components of the dipolar and chemical shielding tensors. However, care must be exercised to preserve the relative orientations of the dipolar and chemical shielding principal axis systems when computing the transition frequency. Thus, three transformations are required: the first two relate the principal axis systems of the chemical shielding tensors to the principal axis system of the dipolar tensor (defined by the internuclear vector), and the third transformation relates the internuclear vector to the magnetic field axis. Hence, the observed chemical shift $\omega_{zi}(\vartheta, \phi, \Omega_i)$ of the *i*th proton incorporates the set of Euler angles $\Omega_i = \{\alpha_i, \beta_i, \gamma_i\}$ relating the principal axis of the chemical shielding tensor to that of the dipolar coupling, while the polar angle ϑ and azimuthal angle ϕ relate the orientation of the internuclear vector to the magnetic field direction. The final expression for the chemical shift of the *i*th nucleus for an arbitrary orientation is given by^{46,47}

$$\omega_{zi} = \omega_0 \sigma_i + \omega_0 (8\pi/15)^{1/2} \delta_i \sum_{m'} Y_{2,-m'}(\vartheta, \phi) \times \left[(3/2)^{1/2} D_{0m'}^2(\Omega_i) + \frac{\eta_i}{2} [D_{2m'}^2(\Omega_i) + D_{-2m'}^2(\Omega_i)] \right] \quad (75)$$

where $D_{m,m'}^l(\Omega)$ are elements of the Wigner rotation matrix, Y_l^m are the spherical harmonics, $\omega_0 = -\gamma_n B_0$, $\delta_i = \sigma_{ZZ}^i -$

$1/3Tr\sigma^i$ is the chemical shift anisotropy, and $\eta_i = (\sigma_{YY}^i - \sigma_{XX}^i)/\delta_i$ is the asymmetry parameter.

The diagonalization of this Hamiltonian led to the eigenstates given by equations (10)–(13), and the initial density matrix describing the spins at the moment of chemisorption was previously derived (equation (16)). When the distribution of reaction times is broad compared to the period of the coherent evolution at the surface, the time-averaged density operator, with vanishing off-diagonal elements, is obtained. This is likely to be a realistic model of the dynamics in view of the decay of coherent oscillations associated with a powder distribution of proton dipolar couplings and shifts. The signal derived from the time-averaged density matrix (equation (26)), together with equation (75), is the starting point for the line shape powder averaging. Population inversion across two of the four dipole-allowed transitions results in powder patterns with antiphase character. Destructive interference between different transitions occurs due to the variation of the phase of the transitions across the powder pattern, resulting in a loss of signal intensity.

Figure 14 shows a simulation of the surface PASADENA spectrum using the following parameters: interproton distance of 0.26 nm ($\nu_D = 6$ kHz); principal components of the chemical shielding tensors, $\sigma_1 = \{5.0, 0.8, -3.8\}$ and $\sigma_2 = \{2.5, 1.0, -5.4\}$; Euler angles (in degrees) $\Omega_1 = \{0, 71, 37\}$, $\Omega_2 = \{116, 71, 21\}$. Although the chemical shift tensor information is not considered reliable in this simulation due to the large range of tensor parameters that gave a reasonable match to the spectrum, fits of the simulation to the experimental spectrum were optimized at an interproton distance of either 0.18 or 0.25 nm. A 2D NMR nutation study by Carson resulted in an optimal fit at an interproton separation of 0.25 nm.⁴⁸

Figure 14 Simulated PASADENA lineshape in a powdered sample with an interproton distance of 2.6 Å (dipolar coupling parameter $\nu_D = 6$ kHz). The principle components of the chemical shift tensor (in kHz) are $\sigma_1 = \{5.0, 0.8, -3.8\}$ and $\sigma_2 = \{2.5, 1.0, -5.4\}$ and the Euler angles (in degrees) are $\Omega_1 = \{0, 71, 37\}$ and $\Omega_2 = \{116, 71, 21\}$. The spectrum was simulated using a $\pi/4$ detection pulse

9 CONCLUSIONS

NMR is a powerful technique for the elucidation of structure and dynamics at the molecular level, but a problem that is frequently encountered in this form of low energy spectroscopy is the issue of signal-to-noise. The search to find new methods to obtain sensitivity enhancement in NMR is ongoing, and there is currently a substantial effort by numerous research groups to improve, generalize and demonstrate the utility of existing techniques. These include optical pumping, microwave dynamic nuclear polarization, chemically induced dynamic nuclear polarization and cross-polarization. Incremental increases can be gained by further increases in magnetic field strength, but there are clear practical (and economical!) limits of this brute force approach. Decreasing the temperature can also help in certain studies, but the experimental conditions and spin-lattice relaxation considerations limit the generality of this approach. Unfortunately, there is no single method that is completely general, and the choice of which method to employ depends on the specific characteristics of the system of interest as well as the desired experimental conditions.

The PASADENA effect is an important new addition to this arsenal of NMR signal enhancement techniques, and it is the method of choice for the study of catalytic hydrogenation kinetics and mechanism. Since the original proposal and experimental demonstration using Wilkinson's catalyst, the phenomenon has been confirmed with many other hydrogenation catalysts, and there have been dozens of pulse sequence extensions and chemical applications of the basic phenomenon, a few of which have been reviewed here.

In theory, the NMR signal that can be obtained by the PASADENA effect using 100% p -H₂ approaches the value that would be obtained for a fully polarized nuclear spin system. In the variation of the PASADENA effect known as ALTADENA, theory indicates that perfect nuclear spin order is in principle obtainable. There are very few examples, if any, of NMR signal enhancement techniques that can produce such a high degree of spin order under ambient sample conditions. The signal enhancement that is available by the PASADENA effect will surely lead to many new discoveries pertaining to hydrogenation chemistry.

1 INTRODUCTION

A composite pulse is a small number of contiguous, or near-contiguous, rf pulses with different phase. The composite pulse emulates the effect of a simple rf pulse, but has an inbuilt compensatory mechanism which renders it less sensitive to common experimental imperfections. Composite pulses may be compensated against the inevitable spread in the amplitude of the applied rf field over a sample of finite extent; they may be rendered insensitive to the limited strength of the applied rf field compared with the interactions of the spins with each other (spin–spin couplings) or with the molecular electron clouds (chemical shifts). In some cases other common pulse imperfections such as pulse shape errors are compensated. Composite pulse sequences are useful in a wide range of experimental situations in NMR. They are particularly important when critical experiments are performed in difficult situations, such as when the sample is large compared with the rf coil, absorbs rf fields strongly, or when the attainable field is restricted because heating must be avoided.

A case of particular importance is broadband heteronuclear spin decoupling (see *Decoupling Methods*). Here a continuous train of composite pulses is applied to one spin species while a different spin species is observed. Suitable composite pulse sequences cause the spin system to evolve as if the heteronuclear spin–spin couplings were absent. The minimization of heating effects is particularly demanding in this application since the rf field may be applied continuously over a period of seconds. Composite pulse techniques have allowed a large reduction in the usable rf power and are now almost universal in heteronuclear liquid state NMR.

Compensation of the nuclear spin dynamics is also important in solid state NMR. Controlled spin manipulations can be achieved even when the achievable rf field is comparable with magnetic dipole–dipole couplings or electric quadrupole couplings. They are used in quadrupole echo experiments, methods to determine the orientation dependence of spin–lattice

relaxation times, and for heteronuclear decoupling. Composite pulses have also been designed for NMR in zero magnetic field¹ (see *Zero Field NMR*), in nuclear quadrupole resonance (NQR) spectroscopy^{2,3} and even in coherent optical experiments.^{4–6}

The original idea of compensating rf pulses for imperfections has been extended in several additional directions.

1. Composite pulses have been designed with an *exaggerated* sensitivity to the rf field amplitude. The response with respect to the rf field strength may be tailored so that there is strong uniform excitation within a given range and minimal excitation otherwise. In combination with careful rf coil design, such composite pulses comprise a means of spatial localization (see *Rotating Frame Methods for Spectroscopic Localization*) of the nuclear spin signal.
2. Composite pulses have been designed with a carefully-tailored *frequency response*, i.e. dependence of spin dynamics on chemical shifts. This can be used, for example, in the suppression of undesirable NMR signals from solvent spins (see *Water Suppression in Proton MRS of Humans and Animals*).
3. Composite pulses may be constructed which simulate the effect of arbitrary rf phase shifts on spectrometers which are equipped only to produce 90° phase steps.
4. Many experiments in coupled spin systems require some knowledge of the typical values of spin–spin coupling constants or quadrupole couplings. In practice, there is some spread in the magnitudes of these interactions, leading to a reduced experimental efficiency or, in some cases, extra peaks in two-dimensional spectra. By making analogies with composite pulses, methods have been designed which are internally compensated against deviations of the couplings from their expected values.
5. Composite pulse sequences closely related to heteronuclear decoupling sequences are widely used for the propagation of spin coherence through extended networks of spin–spin couplings.

The variety of composite pulse sequences, and the range of associated theoretical approaches and applications, is large. The choice of topics covered here is necessarily subjective. A more detailed, and theoretical, review of the field up to 1986 is given by Levitt.⁷

2 NOTATION

Consider a spin species I with magnetogyric ratio γ_I , exposed to a strong static magnetic field B_0 . The Larmor frequency of the spins, neglecting for the moment chemical shifts and spin–spin couplings, is given by $\omega_0 = -\gamma_I B_0$, in units of rad s^{-1} . For example, the Larmor frequency $\omega_0/2\pi$ for protons in a field $B_0 = 11.74 \text{ T}$ is approximately -500 MHz .

During an rf pulse, an additional oscillating magnetic field is applied. The oscillation frequency of the applied field will be denoted by ω_1 (this conforms to the notational convention used in this Encyclopedia, but the reader is warned against conflicts with much published work). Usually ω_1 is very close to the Larmor frequency of the spins ω_0 .

For high-field NMR, the relevant component of the rf magnetic field is perpendicular to the static magnetic field, and rotates around B_0 in the same sense as the precessional motion of the spins. The *amplitude* of the relevant component

of the oscillating rf field is denoted by B_1 . This is usually written in terms of the *nutaton frequency*

$$\Omega_1 = -\gamma_I B_1 \quad (1)$$

The nutation frequency $\Omega_1/2\pi$ is usually of the order of kilohertz or tens of kilohertz, and is generally assumed to be positive for convenience (for spins with positive γ_I , this implies that the field component B_1 is taken to be negative).

In general, Ω_1 is spatially inhomogeneous, i.e. differs from place to place in the sample. This will sometimes be stressed by writing $\Omega_1(\mathbf{r})$, where $\mathbf{r}$ is a spatial coordinate.

To set the pulse durations it is necessary to assume a certain ‘nominal’ nutation frequency Ω_1^0 . This represents roughly the most probable value of Ω_1 over the sample volume, and is normally determined by some simple experimental procedure. For example, the ‘90° pulse length’ τ_{90} can be set by finding the pulse duration giving the maximum NMR signal. The nominal nutation frequency Ω_1^0 is then defined through the relationship:

$$\Omega_1^0 \tau_{90} = \pi/2 \quad (2)$$

Other experimental procedures may give slightly different estimates. This does not matter very much. Ω_1^0 should simply be somewhere near the center of the actual $\Omega_1(\mathbf{r})$ distribution.

The *duration* τ_p of a single rf pulse is conveniently denoted in terms of Ω_1^0 by the ‘nominal flip angle’ β_p^0 , defined by

$$\beta_p^0 = \Omega_1^0 \tau_p \quad (3)$$

A rectangular rf pulse can therefore be specified by using the two angles β_p^0 (for the duration) and ϕ_p (for the rf phase), and will be denoted $(\beta_p^0)_{\phi_p}$, with the angles given in degrees. Otherwise, radians will be used. For example, 90₄₅ denotes a rectangular rf pulse with an rf phase $\phi_p = \pi/4$ and a pulse duration $\tau_p = (\pi/2)/\Omega_1^0$.

A composite pulse is simply a sequence of single rectangular pulses. For simplicity, only *contiguous* composite pulses will be considered here, i.e. there are no spaces between the pulses. All component pulses are assumed to have the same frequency, although this is not always the case in practice.⁸ The composite pulse sequence is written in chronological order from left to right. For example, 90₄₅180₀ denotes a rectangular rf pulse with rf phase of $\pi/4$ and a duration of $\tau_p = (\pi/2)/\Omega_1^0$, immediately followed by another rectangular pulse with an rf phase of zero and a duration of $\tau_p = \pi/\Omega_1^0$.

Sometimes it is necessary to denote an overall phase shift of an entire group of pulses. This is done using square brackets, for example $[(\beta_1^0)_{\phi_1} (\beta_2^0)_{\phi_2}]_{\Phi}$, which is equivalent to $(\beta_1^0)_{\phi_1+\Phi} (\beta_2^0)_{\phi_2+\Phi}$.

A pulse sequence $\mathbb{S}$ with an element $\mathbb{E}$ missing at the front will be denoted by $\mathbb{E}^{-1}\mathbb{S}$. For example, if a sequence $\mathbb{S}$ is given by $\mathbb{S} = 90_{45}180_0 90_{180}$, then $(90_{45})^{-1}\mathbb{S}$ is given by $180_0 90_{180}$. Similarly, $\mathbb{S}(90_{180})^{-1}$ is given by $90_{45}180_0$. The pulse sequence $\mathbb{E}^{-1}\mathbb{S}\mathbb{E}$ derived from $\mathbb{S}$ by taking the element $\mathbb{E}$ from the front to the back is a *cyclic permutation* of $\mathbb{S}$.

The chronological reverse of a pulse sequence $\mathbb{S}$ is denoted by $\mathbb{S}^{\text{rev}}$. In the example above, $\mathbb{S}^{\text{rev}}$ would be $90_{180}180_0 90_{45}$.

3 PULSE IMPERFECTIONS

Two common causes of imperfect pulse performance are: (i) lack of uniformity in the applied rf field, and (ii) limited amplitude of the rf field compared with the other interactions experienced by the spins.

3.1 Radiofrequency Field Inhomogeneity

The amplitude of the relevant rf field component varies from place to place in the sample. The rf field experienced by the spins is conveniently represented by the dimensionless parameter Ω_1/Ω_1^0 , which is equal to 1.0 for the nominal rf field. In practice, Ω_1/Ω_1^0 deviates from unity by a few percent in a well-designed high-resolution NMR probe, but the deviations may exceed 20% for a surface coil in NMR imaging (see *Surface Coil NMR: Detection with Inhomogeneous Radiofrequency Field Antennas*).

3.2 Limited rf Field Amplitude

The usable rf field amplitude is always limited, either because sample heating must be minimized, or because of the risk of electrical failure in the amplifiers or rf coil. Magnetic fields associated with chemical shifts or spin couplings compete with the rf field during the pulse and bring about a degradation in pulse performance.

3.2.1 Isotropic Liquids

In isotropic liquids, spin–spin couplings are small. Imperfect pulse performance at low rf fields is caused mainly by chemical shifts and field inhomogeneities which cause the Larmor frequency of the spins to differ from site to site in the sample. If the electronic shielding constant for a site is σ^j , and the applied magnetic field is B_0 , the Larmor frequency ω_0^j of that site is given by:

$$\omega_0^j = -\gamma_I B_0(1 - \sigma^j) \quad (4)$$

The *resonance offset* $\Delta\omega^j$ of a set of chemically equivalent spins I_j is equal to the difference between the Larmor frequency and the irradiation frequency:

$$\Delta\omega^j = \omega_0^j - \omega_1 \quad (5)$$

For a sample containing only one chemical site, in a perfectly homogeneous static magnetic field, $\Delta\omega^j$ may be set to zero simply by using an rf ω_1 exactly equal to the chemically-shifted Larmor frequency ω_0^j . However, when the sample contains many different chemical sites, or when the static field is inhomogeneous, resonance offset effects are inevitable.

The seriousness of resonance offset effects may be quantified by the dimensionless parameter $\Delta\omega^j/\Omega_1^0$ which will be called the *relative resonance offset*. For high-resolution proton spectroscopy, the magnitude of the relative offset is typically less than 0.1. For decoupling experiments, and for composite pulses on nuclei with larger chemical shift ranges, relative offsets of 1.0 or more are common.

The resonance offsets $\Delta\omega^j$ may have either algebraic sign, depending on whether the Larmor frequency is higher or lower than the irradiation frequency. For a conventionally presented spectrum of nuclei with a positive magnetogyric ratio such as ^1H or ^{13}C , spins with positive $\Delta\omega^j$ appear on the right-hand side of the spectrum. (Remember that the Larmor frequency ω_0^j and irradiation frequency ω_1 are close to $-\gamma IB_0$ and are therefore negative.)

3.2.2 Anisotropic Liquids and Solids

In anisotropic systems, the situation is more complicated as there are many spin interactions large enough to compete with the applied rf field. For spins $I \geq 1$, quadrupolar interactions are usually dominant. For ^1H spins in solids, on the other hand, through-space dipole–dipole interactions are large and produce imperfect pulse performance. For dilute spin- $\frac{1}{2}$ nuclei like ^{13}C and ^{15}N , chemical shifts often dominate and the situation is similar to that in isotropic liquids, although the magnitude of the interactions is larger.

The anisotropic case is examined in Section 6 of this article. In most of the following discussion, isotropic liquid phase is assumed and resonance offset effects quantified by the parameter $\Delta\omega^j/\Omega_1^0$.

3.3 Other Pulse Imperfections

There are a number of other common pulse imperfections, such as errors in the profile of the pulse in time, errors or instability in the rf phase, and induced fields associated with coupling of the nuclear spin magnetization to the resonant detection coil (see *Concentrated Solution Effects*). Generally speaking these errors are left uncompensated by composite pulses, although there are exceptions. In particular, composite pulses always assume highly accurate and stable rf phases. Fortunately, digital electronic synthesis of the rf signals generally ensures precise phases in modern instruments.

4 AN EXAMPLE OF ERROR COMPENSATION: THE COMPOSITE PULSE $90_{90}180_{90}90_{90}$

To introduce the concept of error compensation, consider one of the common tasks of a 180° pulse, namely the sign inversion of the z component of spin angular momentum. This corresponds to an exchange of spin state populations and is often exploited for measuring relaxation time constants (see *Relaxation: An Introduction*).

4.1 Single Pulse Propagator

Consider a single rectangular pulse of nominal flip angle β_p^0 and phase ϕ_p . If the rf field is much larger than the spin–spin couplings, and β_p^0 is not extremely large, then the pulse duration is short on the timescale of spin–spin couplings and the individual spin states undergo a simple rotation in

three-dimensional space. The quantum states $|\psi\rangle^j$ of spins I_j before and after a pulse p are related by

$$|\psi\rangle_{\text{after}}^j = \hat{U}_p^j |\psi\rangle_{\text{before}}^j \quad (6)$$

where $\hat{U}_p^j$ is the rotating frame pulse *propagator* for spins I_j , given by

$$\hat{U}_p^j = \exp\{-i\xi_p^j \hat{\mathbf{I}}_j \cdot \mathbf{n}_p^j\} \quad (7)$$

ξ_p^j is the rotation angle of spins I_j during pulse p , and $\mathbf{n}_p^j$ is the rotation axis.

For an *ideal pulse* of nominal flip angle β_p^0 and phase ϕ_p , the rotation angle is $\xi_p^j = \beta_p^0$, and the rotation axis is $\mathbf{n}_p^j = \mathbf{e}_x \cos \phi_p + \mathbf{e}_y \sin \phi_p$, where $\mathbf{e}_x$ and $\mathbf{e}_y$ are unit vectors along the x and y axes. If there are finite resonance offset effects or rf amplitude errors, on the other hand, the rotation parameters are

$$\xi_p^j = \beta_p^0 \sqrt{\frac{(\Omega_1)^2 + (\Delta\omega^j)^2}{(\Omega_1^0)^2}} \quad (8)$$

$$\mathbf{n}_p^j = \mathbf{e}_z \cos \theta^j + \mathbf{e}_x \sin \theta^j \cos \phi_p + \mathbf{e}_y \sin \theta^j \sin \phi_p \quad (9)$$

where the angle θ^j is

$$\tan \theta^j = \Omega_1 / \Delta\omega^j \quad (10)$$

4.2 Single 180_0 Pulse

Consider now the specific case of a 180_0 pulse, i.e. $\beta_p^0 = \pi$ and $\phi_p = 0$. For small offsets $\Delta\omega^j/\Omega_1^0$, the propagator is simply

$$\hat{U}_p^j \simeq \exp\{-i\xi_p^j \hat{I}_{jx}\} \quad (11)$$

with

$$\xi_p^j = \pi \Omega_1 / \Omega_1^0 \quad (12)$$

indicating that the spin angular momentum turns through an angle ξ_p^j about the x axis of the rotating reference frame. Depending on the rf field Ω_1 , this angle can be either smaller or greater than the nominal flip angle $\beta_p^0 = \pi$.

The transformation of z angular momentum by an imperfect 180_0 pulse is readily understood geometrically. An ensemble of spins I_j with finite polarization along the z axis has a spin density operator $\hat{\sigma}_{\text{before}} = \hat{I}_{jz}$ (inessential constants being omitted). This can be represented as an angular momentum vector along the z axis of the rotating reference frame [Figure 1(a)]. After the pulse the density operator is

$$\begin{aligned} \hat{\sigma}_{\text{after}} &= \hat{U}_p^j \hat{I}_{jz} \hat{U}_p^{j\dagger} \\ &= \hat{I}_{jz} \cos \xi_p^j - \hat{I}_{jy} \sin \xi_p^j \end{aligned} \quad (13)$$

Figure 1 Effect of an imperfect rf field on a 180_0 pulse. (a) The equilibrium spin magnetization is represented as a unit vector along the z axis of the rotating reference frame. (b) For nominal rf fields ($\Omega_1 = \Omega_1^0$), the magnetization vector rotates through 180° around the x axis, ending up exactly at the $-z$ axis. (c) For rf fields stronger than the nominal, the magnetization vector overshoots the $-z$ axis. (d) For rf fields weaker than the nominal, the vector falls short of the $-z$ axis. In both cases, the z component of the final vector is larger than -1

This can be understood as a rotation of the angular momentum of the spin ensemble around the x axis through an angle ξ_p^j . For nominal rf fields, $\xi_p^j = \pi$ and the spin angular momentum is along the $-z$ axis after the pulse [Figure 1(b)]. For rf fields larger than the nominal [Figure 1(c)], the vector ‘overshoots’ the $-z$ axis, and for weak rf fields, the vector falls short [Figure 1(d)]. The transformed z angular momentum of spins I_j , given by the parameter

$$R_{zz}^j = \text{Tr}\{\hat{U}_p^j \hat{I}_{jz} \hat{U}_p^{j\dagger} \hat{I}_{jz}\} / \text{Tr}\{\hat{I}_{jz}^2\} = \cos \xi_p^j \quad (14)$$

is equal to -1 for an ideal 180_0 pulse, but is larger than -1 if the pulse is imperfect [Figure 2(a)]. For small rf field errors, the transformed z angular momentum is

$$R_{zz}^j \simeq -1 + \frac{1}{2}\pi^2 \left(\frac{\Omega_1 - \Omega_1^0}{\Omega_1^0} \right)^2 \quad (15)$$

i.e. it is quadratically dependent on the rf error. In practice this means that the degree of spin population inversion is spatially dependent, with detrimental experimental consequences.

Figure 2 Transformation parameters of z angular momentum R_{zz}^j for a single 180_0 pulse (—), and a composite $90_{90}180_090_{90}$ pulse (---). (a) Dependence of R_{zz}^j on the rf field Ω_1/Ω_1^0 . (b) Dependence of R_{zz}^j on the relative resonance offset $\Delta\omega^j/\Omega_1^0$

4.3 Composite Pulse $90_{90}180_090_{90}$

The imperfect transformation of z angular momentum may be corrected⁹ by using a composite pulse $90_{90}180_090_{90}$ as illustrated in Figure 3. The trajectories of the tips of a family of vectors, all starting out along the z axis, are tracked out during the pulse sequence. The vectors in the family correspond to different rf field values; to simplify the picture, all represent rf fields weaker than the nominal.

During the first 90_{90} element, all vectors rotate around the y axis, starting at the z axis and turning towards the x axis. An ideal 90_{90} pulse would take them exactly to the x axis, but, as the fields are weak, they fall short. The next 180_0 element rotates these vectors around the x axis. After this element, the vectors still lie approximately in the xz plane, but they now lie in the southern hemisphere of the unit sphere. Indeed, the tips of the vectors after the first and second pulses are related as approximate mirror images in the xy plane. The last 90_{90} element again rotates the vectors around the y axis, through exactly the same angle as the first element. The error compensation works as follows; just those vectors which lag the most after the first pulse are helped the most by the second pulse, so that they don’t have as far to go during the last pulse. On the other hand, if the rf field is close to the nominal, the

Figure 3 Geometrical mechanism of rf field compensation for the composite pulse $90_{90}180_090_{90}$

vectors are already taken nearly to the x axis by the first pulse, so that they are almost unaffected by the second pulse. Again they are in the right position to be taken to the $-z$ axis by the last pulse. Hence the angular momentum vectors for spins in a range of rf fields concentrate near the $-z$ axis at the end of the sequence. A plot of R_{zz}^j against relative rf field Ω_1/Ω_1^0 for the composite pulse $90_{90}180_090_{90}$ is shown by the dashed line in Figure 2(a).

An accurate analysis of the sequence $90_{90}180_090_{90}$ shows¹⁰ that for small resonance offsets the transformed z angular momentum is given by

$$R_{zz}^j = \cos \left\{ 2 \arccos \left[\cos^2 \left(\frac{\pi \Omega_1}{2\Omega_1^0} \right) \right] \right\} \quad (16)$$

For small rf field errors this can be approximated as

$$R_{zz}^j \simeq -1 + \frac{1}{8}\pi^4 \left(\frac{\Omega_1 - \Omega_1^0}{\Omega_1^0} \right)^4 \quad (17)$$

The transformation of z magnetization is sensitive only to the fourth order in rf field error.

It happens that $90_{90}180_090_{90}$ also gives a rather good compensation for resonance offsets, as long as the rf field intensity is close to the nominal. A simulation of R_{zz}^j against resonance offset $\Delta\omega^j/\Omega_1^0$, in the case of an exactly set rf field $\Omega_1 = \Omega_1^0$, is shown in Figure 2(b). The compensation of offset is not very exact, but quite broadband, giving fair inversion of z angular momentum for all offsets between $-1.0 \leq \Delta\omega^j/\Omega_1^0 \leq 1.0$.

A picture of what happens when both offset and rf error are introduced at the same time is given in Figure 4(b). This shows a contour plot of R_{zz}^j against resonance offset $\Delta\omega^j/\Omega_1^0$ (horizontal) and rf field Ω_1/Ω_1^0 (vertical). The darkest portions of the plot are regions of excellent population inversion ($R_{zz}^j \leq -0.98$). These regions are far more extensive for $90_{90}180_090_{90}$ than for a single pulse 180_0 [Figure 2(a)]. However, the sequence $90_{90}180_090_{90}$ cannot strictly be said to compensate for *simultaneous* resonance offset and rf field errors. There is trouble if the rf field is weak at the same time as there is a moderate resonance offset. For truly simultaneous compensation, one must use more complicated sequences, such

Figure 4 Contour plots of the parameter R_{zz}^j as a function of rf field Ω_1/Ω_1^0 and resonance offset $\Delta\omega^j/\Omega_1^0$ for four different pulse sequences. Inside the darkest region, the parameter R_{zz}^j is less than -0.98 . Increasingly bright regions are delimited by contours at $\{-0.95, -0.9, -0.8, -0.6, -0.4, \dots\}$. (a) Single pulse 180_0 . (b) Composite pulse $90_{90}180_090_{90}$. (c) Composite pulse $270_{180}360_090_{90}270_{270}360_090_{90}$. (d) Composite pulse $180_{30}180_{205}180_{230}180_{85}180_0180_{85}180_{230}180_{205}180_{30}$

as

$$270_{180}360_090_{90}270_{270}360_090_{90} \quad (18)$$

whose performance is illustrated in Figure 4(c).¹¹

The above analysis considered only the z component of spin angular momentum. In general, other angular momentum components are also important. Figure 5 illustrates the subtleties which arise when composite pulses are applied to general states of the spin ensemble. The spin density operator is represented not as a vector but as a full three-dimensional object with low symmetry, here a simple L shape.

In Figure 5(a) the L shape is subjected to a sequence of three rotations, a 90° rotation around the y axis, followed by a 180° rotation around the x axis, and a 90° rotation around the y axis again. These three rotations may be shown to be equivalent to a single rotation, through 180° around the x axis, as shown by the final position in Figure 5(a).¹² The composite pulse $90_{90}180_090_{90}$ is equivalent to a single 180_0 , if all pulses are ideal.

Figure 5(b) illustrates the behavior of the composite pulse if the rf field is somewhat weaker than nominal. After the three mis-set rotations, the long arm of the L is taken almost exactly to the $-z$ axis, as expected from Figure 3. However, the L shape is also rotated around the z axis, as can be seen by comparing the final positions in Figure 5(a) and (b). In the language of nuclear spin dynamics, the compensated population inversion is accompanied by a *phase shift* of the spin coherences. Such induced *phase distortions* are a common feature of most composite pulses, and must carefully be taken into account in general applications.

Figure 5 Transformations of a three-dimensional object by a succession of three rotations. (a) A 90° rotation about the y axis, followed by a 180° rotation about the x axis, followed by a 90° rotation about the y axis. (b) A 80° rotation about the y axis, followed by a 160° rotation about the x axis, followed by a 80° rotation about the y axis

5 COMPOSITE PULSES: SPIN COUPLINGS IGNORED

The response of a general spin system to a composite pulse raises complex issues. Fortunately, the treatment is greatly simplified if the composite pulse is very short compared with the spin–spin coupling constants. Under this approximation, all rf pulses induce simple three-dimensional rotations of the individual spin angular momenta. Such composite pulses can be considered manifestations of the three-dimensional rotation group, and are amenable to geometric representation.

This type of composite pulse only works properly if it is short compared with the timescale set by spin–spin couplings and spin relaxation. This condition is usually readily satisfied in isotropic liquids. Breakdown of this assumption eventually sets a limit on the length of usable sequences.

This restriction should not be taken to imply that such composite pulses can only be applied to systems without spin–spin couplings. The point is merely that the couplings can be ignored *during* the composite pulse. The spin–spin couplings can still be active during the much longer periods *between* the pulses.

A smaller group of composite pulses (discussed in Section 6) takes into account explicitly the spin couplings during the pulse. The dynamics of the spins cannot then be described as rotations in a three-dimensional space.

5.1 Composite Pulse Propagator

Consider a composite pulse with n pulse elements, applied to a system of N coupled spins. If the spin–spin couplings are neglected, the overall propagator $\hat{U}$ of the entire spin system can be factorized into a product of individual propagators $\hat{U}^j$, one for each spin:

$$\hat{U} \simeq \hat{U}^1 \hat{U}^2 \dots \hat{U}^N \quad (19)$$

The individual spin propagators $\hat{U}^j$ all commute, so equation (19) can be written in any order. Each overall spin propagator $\hat{U}^j$ is, in turn, a product of spin rotations $\hat{U}_p^j$ corresponding to the individual pulses p :

$$\hat{U}^j = \hat{U}_n^j \dots \hat{U}_2^j \hat{U}_1^j \quad (20)$$

$\hat{U}_p^j$ is given in equation (7). The operators $\hat{U}_p^j$ do not commute, so the product must be written in strict chronological order from right to left.

Since any product of rotations is another rotation, the overall composite pulse propagator for each individual spin I_j is also a rotation operator, and can be written in the form

$$\hat{U}^j = \exp\{-i\tilde{\xi}^j \hat{I}_j \cdot \tilde{\mathbf{n}}^j\} \quad (21)$$

where $\tilde{\xi}^j$ is the overall rotation angle, and $\tilde{\mathbf{n}}^j$ is the overall rotation axis.

There is another way of writing equation (21), which brings out more clearly the ‘phase-distortion’ properties of the composite pulse. Any rotation can be expressed as three consecutive rotations, about the z axis, the y axis, and the z axis again. The composite pulse propagator can therefore be written

$$\hat{U}^j = \exp\{-i\tilde{\gamma}^j \hat{I}_{jz}\} \exp\{-i\tilde{\beta}^j \hat{I}_{jy}\} \exp\{-i\tilde{\alpha}^j \hat{I}_{jz}\} \quad (22)$$

where the three angles $\{\tilde{\alpha}^j, \tilde{\beta}^j, \tilde{\gamma}^j\}$ are called the *Euler angles* for the overall rotation.¹³ In general, the Euler angles depend on the parameters Ω_1/Ω_1^0 and $\Delta\omega^j/\Omega_1^0$, and are different for each set of spins I_j .

5.2 Classification of Composite Pulses

The properties of composite pulses are defined by the dependence of the three Euler angles $\{\tilde{\alpha}^j, \tilde{\beta}^j, \tilde{\gamma}^j\}$ on the imperfection parameters $\Delta\omega^j/\Omega_1^0$ and Ω_1/Ω_1^0 .

The central angle $\tilde{\beta}^j$ is the most important. If $\tilde{\beta}^j$ is close to some angle Θ , the composite pulse behaves ‘like’ an ideal pulse of nominal flip angle Θ . The composite pulse is then called a *composite Θ pulse*. For example, $90_0 180_0 90_0$ is a composite 180° pulse since $\tilde{\beta}^j$ is close to 180° for small values of $\Delta\omega^j/\Omega_1^0$ and Ω_1/Ω_1^0 .

^cThe range of offset values for which the angle β^j is between 80° and 100°, at nominal rf field.

5.2.1 Broadband Composite Pulses

Often, the composite pulse is designed such that $\tilde{\beta}^j$ remains close to some value Θ over a range of rf field or resonance offset which is larger than for a single pulse. The composite pulse is then called a *broadband composite Θ pulse*.

The range of rf field or resonance offset for which $\tilde{\beta}^j$ is ‘close’ to Θ is called the *compensation bandwidth*. The compensation bandwidths of some selected composite pulses are given in Tables 1 and 2. The tabulated figures indicate the range of $\Delta\omega^j/\Omega_1^0$ and Ω_1/Ω_1^0 within which $\tilde{\beta}^j$ is within 10° of the flip angle Θ . For example, for the composite pulse 90₉₀180₀90₉₀, the angle $\tilde{\beta}^j$ is between 170° and 190° for all values of rf field in the range $0.81 \leq \Omega_1/\Omega_1^0 \leq 1.19$, if the resonance offset is zero. Similarly, $\tilde{\beta}^j$ is between 170° and 190° for all values of resonance offset in the range $-0.09 \leq \Delta\omega^j/\Omega_1^0 \leq 0.09$, providing the rf field is nominal. Parameter ranges which are extended with respect to a single rf pulse are indicated in bold type. Those which are more restricted than for a single pulse are in italics. For example, the sequence 180₁₂₀180₂₄₀180₁₂₀ tolerates a wider range of rf field strengths than a single 180₀ pulse, but only if the resonance offset is kept within stringent limits.

Since R_{zz}^j is equal to $\cos\tilde{\beta}^j$, the quoted bandwidths also apply to the corresponding transformations of z angular momentum. For composite 180° pulses, R_{zz}^j is less than

−0.984 within the quoted bandwidths; for composite 90° pulses, R_{zz}^j is between −0.17 and +0.17 over the tabulated compensation bands.

This bandwidth definition does not yet say anything about the angles $\tilde{\alpha}^j$ and $\tilde{\gamma}^j$. The behavior of these angles introduces further nuances:

1. For *variable rotation composite pulses*, the Euler angles $\tilde{\alpha}^j$ and $\tilde{\gamma}^j$ are unconstrained, and may vary arbitrarily within the compensation band.
2. For *constant rotation composite pulses*, the only variations in $\tilde{\alpha}^j$ and $\tilde{\gamma}^j$ over the compensation band keep the overall rotation operator $\tilde{U}^j$ close to that generated by an ideal Θ_0 pulse.⁴

In Table 3 and 4, some constant rotation composite pulses are listed, together with the ranges of $\Delta\omega^j/\Omega_1^0$ and Ω_1/Ω_1^0 for which they provide a rotation close to the ideal. The compensation range of such composite pulses is more difficult to define than for variable rotation composite pulses, since all three Euler angles are involved. The tabulated constant rotation bandwidths are based upon the values of the angle $\tilde{\xi}_\Delta^j$, defined by the equation

$$\hat{U}^j = \exp\{-i\Theta\hat{I}_{jx}\} \exp\{-i\tilde{\xi}_\Delta^j \hat{\mathbf{I}}_j \cdot \mathbf{n}_\Delta^j\} \quad (23)$$

where $\tilde{U}^j$ is given by equation (21) and $\mathbf{n}_\Delta^j$ is a unit vector. $\tilde{\xi}_\Delta^j$ can be interpreted as the ‘deviation angle’ between the actual

^bThe range of rf field values for which the angle $\tilde{\xi}_\Delta^j$ is less than 10°, at zero resonance offset.

^cThe range of offset values for which the angle $\tilde{\xi}_\Delta^j$ is less than 10°, at nominal rf field.

rotation $\tilde{U}^j$ and the desired ideal rotation. If the rotation is already ideal, $\tilde{\xi}_\Delta^j$ is equal to zero. In terms of the Euler angles, it can be shown that $\tilde{\xi}_\Delta^j$ is given by

$$\cos(\tilde{\xi}_\Delta^j/2) = \cos(\tilde{\beta}^j/2) \cos(\Theta/2) \cos\left(\frac{\tilde{\alpha}^j + \tilde{\gamma}^j}{2}\right) + \sin(\tilde{\beta}^j/2) \sin(\Theta/2) \sin\left(\frac{\tilde{\alpha}^j - \tilde{\gamma}^j}{2}\right) \quad (24)$$

The tabulated constant rotation bandwidths indicate the range of $\Delta\omega^j/\Omega_1^0$ and Ω_1/Ω_1^0 for which the ‘deviation angle’ $\tilde{\xi}_\Delta^j$ is always less than 10°. Within these parameter ranges the composite pulses may be used to replace the single pulse, independent of the experimental context.

The distinction between the different types of composite pulse is illustrated in Figure 6. This shows the dependence of the angles $\tilde{\beta}^j$ and $\tilde{\xi}_\Delta^j$ on the rf field Ω_1/Ω_1^0 , for the variable rotation composite pulse 90₉₀180₀90₉₀ and the constant rotation sequence 180_{104.5}360_{313.4}180_{104.5}180₀.¹⁵ In both cases, $\tilde{\beta}^j$ is kept close to 180° over a range of rf fields, but $\tilde{\xi}_\Delta^j$ is kept low only for the second sequence. The sequence 180_{104.5}360_{313.4}180_{104.5}180₀ behaves similarly to an ideal pulse 180₀ over the entire compensation band.

5.2.2 Narrowband and Band-Reject Composite Pulses

For broadband composite pulses, $\tilde{\beta}^j$ is kept almost constant over a certain range of rf fields or resonance offsets. This

is not the only possible mode of control of $\tilde{\beta}^j$. Some other possibilities are:

1. For *narrowband composite pulses*, $\tilde{\beta}^j$ is kept close to zero over a wide range of parameters, except for certain special values, where $\tilde{\beta}^j$ is close to the nominal flip angle Θ of the composite pulse. Narrowband composite pulses can be used for selecting NMR signals originating in spatial regions with defined values of the rf field amplitude.
2. A *band-reject composite pulse* resembles a broadband composite pulse except for a ‘hole’ in the excitation around some special value of rf field or offset frequency, i.e. $\tilde{\beta}^j$ is large over a wide range except in a narrow region where it approximates zero. Composite pulses with band-reject characteristics for offset $\Delta\omega^j/\Omega_1^0$ can be used for solvent peak suppression.

Most of this article concerns broadband composite pulses. The other possibilities are treated briefly in Section 5.6

5.3 Coherence Transfer Amplitudes

To appreciate the practical significance of the angles $\tilde{\alpha}^j$ and $\tilde{\gamma}^j$, consider the case where the composite pulse is applied to a weakly coupled system of N spins, prepared such that the density operator contains coherences σ_{rs} between two spin eigenstates $|r\rangle$ and $|s\rangle$. In general, the composite pulse sequence converts this coherence partially to another coherence σ_{tu} , between eigenstates $|t\rangle$ and $|u\rangle$. The amplitude for this particular coherence transfer process is written $Z_{rs\ tu}$.

Figure 6 Performance of the single pulse 180_0 (—), composite pulse $90_{90}180_090_{90}$ (---), and composite pulse $180_{104.5}360_{313.4}180_{104.5}180_0$ (....) as a function of rf field. (a) Euler angle β^j . (b) Deviation angle ξ_{Δ}^j . The curves for the single 180_0 pulse and composite pulse $90_{90}180_090_{90}$ are superimposed in (b)

The manipulation of spin state populations may be handled by taking the case $r = s$ or $t = u$ (see *Molecular Motions: T_1 Frequency Dispersion in Biological Systems*).

It may be shown that for a composite pulse with a propagator defined by equation (22), within its compensation band, the amplitude for the coherence transfer process is given by

$$Z_{rstu} \simeq \exp \left\{ -i \sum_j [(\bar{\gamma}^j + \pi/2) p_j^{(tu)} + (\bar{\alpha}^j - \pi/2) p_j^{(rs)}] \right\} Z_{rs tu}^0 \quad (25)$$

where $p_j^{(tu)} = m_j^{(t)} - m_j^{(u)}$, $p_j^{(rs)} = m_j^{(r)} - m_j^{(s)}$, and $m_j^{(s)}$ is the z angular momentum of spin I_j in the eigenstate $|s\rangle$ (weak coupling is assumed). Z_{rstu}^0 denotes the coherence transfer amplitude for a strong ideal pulse of flip angle β^0 .

The experimental significance of the angles $\bar{\alpha}^j$ and $\bar{\gamma}^j$ depends on the quantum numbers characterizing the coherence transfer process. If only populations are involved ($p_j^{(tu)} = p_j^{(rs)} = 0$), the Euler angles $\bar{\alpha}^j$ and $\bar{\gamma}^j$ may be ignored. If coherences are involved, on the other hand, $\bar{\alpha}^j$ and $\bar{\gamma}^j$ must be taken into account.

It would therefore seem advisable to use constant rotation composite pulses whenever spin coherences are involved.

However, this is not always the best strategy. Constant rotation composite pulses are often long and have small compensation bandwidths. In many circumstances, variable rotation composite pulses are to be preferred:

1. In heteronuclear experiments, composite pulses applied to one spin species do not affect the phases of coherences associated with a different spin species. For example, variable rotation composite 180° pulses such as $90_{90}180_090_{90}$ may be applied to the I spins in order to change the sign of density operator terms such as $\hat{I}_z \hat{S}_x$. Such manipulations are common in two-dimensional heteronuclear shift correlation experiments (see *Heteronuclear Shift Correlation Spectroscopy*).
2. For some variable rotation composite pulses, the angles $\bar{\alpha}^j$ and $\bar{\gamma}^j$ are linearly dependent on resonant offset $\Delta\omega^j$. In simple experiments involving only one coherence transfer step, phase distortions can then be removed simply by applying a numerical frequency-dependent phase correction to the spectrum.
3. If a phase cycle is performed so as to select signals arising only from *one single coherence transfer pathway* (see *Phase Cycling*), then the angles $\bar{\alpha}^j$ and $\bar{\gamma}^j$ only contribute to a rather harmless overall phase shift of the signal.
4. Even in arbitrary experiments involving many coherence transfer steps and many coherence transfer pathways, it is usually possible to choose variable rotation composite pulses such that the phase shifts induced by one composite pulse are cancelled out by the next composite pulse.^{7,16,17} A general procedure is described in Section 5.5

5.4 Construction of Broadband Composite Pulses

There is a great variety of theoretical approaches to composite pulse construction. The following summary is superficial.

5.4.1 Geometry

The first composite pulse $90_{90}180_090_{90}$ was discovered by the geometrical arguments outlined in Figure 3. This simple method should not be underestimated. It exploits the impressive human faculty of three-dimensional visualization. However, so far, only variable-rotation composite pulses have been derived geometrically. Apart from $90_{90}180_090_{90}$, geometrical reasoning has led to the useful sequences 90_0180_{120} (an rf-compensated 90° pulse with a large bandwidth) and $90_0360_{120}90_0$ (a highly rf-compensated 180° pulse).^{18–20}

5.4.2 Rotation Analysis

Geometrical reasoning may be assisted by mathematical methods such as quaternion algebra²¹. One powerful result is as follows.¹⁰ Suppose a rotation through the angle ξ_1 about the axis $\mathbf{n}_1$ is followed by a rotation through the angle ξ_2 about the axis $\mathbf{n}_2$. The two consecutive rotations are equivalent to a single rotation through the angle ξ_{12} about the axis $\mathbf{n}_{12}$. It is possible to show that ξ_{12} and $\mathbf{n}_{12}$ are given by

$$\left. \begin{aligned} c_{12} &= c_1 c_2 - s_1 s_2 \mathbf{n}_1 \cdot \mathbf{n}_2 \\ s_{12} \mathbf{n}_{12} &= s_1 c_2 \mathbf{n}_1 + c_1 s_2 \mathbf{n}_2 - s_1 s_2 \mathbf{n}_1 \times \mathbf{n}_2 \end{aligned} \right\} \quad (26)$$

where $c_p = \cos(\xi_p/2)$, $s_p = \sin(\xi_p/2)$, $c_{12} = \cos(\xi_{12}/2)$, $s_{12} = \sin(\xi_{12}/2)$.

Using such formulae, it is possible to show, for example, that the Euler angle $\tilde{\beta}^j$ for the composite pulse $90_{90}180_{90}90_{90}$ at resonance offset $\Delta\omega^j = 0$ is given by

$$\cos(\tilde{\beta}^j/2) = \cos^2(\pi\Omega_1/2\Omega_1^0) \quad (27)$$

while for the composite pulse $90_{90}360_{120}90_{90}$ the corresponding Euler angle is

$$\cos(\tilde{\beta}^j/2) = \cos^3(\pi\Omega_1/2\Omega_1^0) \quad (28)$$

The powers of the cosine function on the right-hand sides of these equations indicate an increasing degree of compensation.

Such results are useful for understanding the response of existing composite pulses but have not yet proved very useful for the design of original sequences.

5.4.3 Coherent Averaging Theory

Coherent averaging theory is a form of dynamic perturbation theory, frequently used in multiple pulse sequence development (see *Average Hamiltonian Theory; Line Narrowing Methods in Solids*). (In the present context, coherent averaging theory writes the ‘difference rotation’ of Equation (23) as a convergent series:

$$\tilde{\xi}_\Delta^j \hat{\mathbf{I}}_j \cdot \mathbf{n}_\Delta^j = \tilde{\xi}_\Delta^{j(0)} \hat{\mathbf{I}}_j \cdot \mathbf{n}_\Delta^{j(0)} \hat{\mathbf{I}}_j + \tilde{\xi}_\Delta^{j(1)} \hat{\mathbf{I}}_j \cdot \mathbf{n}_\Delta^{j(1)} + \dots \quad (29)$$

For a given type of imperfection, it is possible to develop simple algebraic equations for the terms $\tilde{\xi}_\Delta^{j(k)}$ as functions of the pulse durations and phases. By solving the equations analytically or numerically, pulse sequences are derived for which as many terms $\tilde{\xi}_\Delta^{j(k)}$ as possible vanish. The more terms that are removed, the higher the degree of compensation.^{15, 22–26}

This approach allows the construction of constant rotation composite pulses. One example is the offset-compensated composite 90° pulses $385_{90}320_{180}25_{90}$.²⁶ A continuous set of offset-compensated constant rotation composite pulses with arbitrary flip angle Θ was derived by exploiting pulse sequence symmetries to reduce the number of simultaneous equations.²⁷ Two such constant rotation offset-compensated composite pulses are the 180° pulse $59_{180}298_{90}59_{180}$ and the 90° pulse $114.3_{180}318.6_{90}114.3_{180}$.²⁷

A continuous set of rf-compensated constant rotation composite pulses has also been found.¹⁵ An rf-compensated rotation with $\tilde{\beta}^j \simeq \Theta$ is generated by the sequence $180_{\phi_1}360_{\phi_2}180_{\phi_1} \Theta_0$ where $\phi_1 = \arccos(-\Theta/4\pi)$ and $\phi_2 = 3\phi_1$. Two examples are the broadband 180° pulse $180_{104.5}360_{313.4}180_{104.5}180_0$ and the broadband 90° pulse $180_{97.2}360_{291.5}180_{97.2}90_0$.

5.4.4 Numerical Optimization

It is also feasible to find composite pulses by fairly straightforward numerical optimization methods. The multidimensional space of pulse durations and pulse phases is searched until a sequence with the required properties is found.^{8, 27–31} Efficient optimization algorithms such as simulated annealing

are often helpful.^{30, 31} Pulse sequence symmetry may be used to reduce the number of independent variables.

Another variant is to extend the bandwidth of an existing composite pulse by adding small extra pulses and optimizing numerically. This can be repeated many times. An example is the composite 180° pulse $158.0_{90}171.2_{180}342.8_{90}145.5_{180}81.2_{90}85.3_{180}$ which has $\tilde{\beta}^j \simeq \pi$ over a wide range $-1.5 \leq \Delta\omega^j/\Omega_1^0 \leq 1.5$.²⁸ A different starting point is provided by analytical results for *smooth* rf waveforms (see *Shaped Pulses*). The composite 180° pulse $64_{232}122_{96}310_{90}122_{96}64_{232}$ was derived this way.³² Wide bandwidth variable rotation composite pulses may be constructed particularly rapidly by allowing the rf frequencies ω_1 of subsequent pulses to be different.⁸

5.4.5 Iterative Expansion

Highly compensated sequences require very many pulses. It is very difficult to find such sequences by theoretical techniques such as coherent averaging theory (since the number of simultaneous equations becomes very large) or by numerical optimization (which eventually resembles searching for a needle in a haystack). A complementary approach is *iterative expansion*.^{23, 33–39} This defines an optimization procedure which (given a suitable starting point) leads inexorably to a sequence with the desired properties. The drawback is that the process is inefficient, often producing extremely long pulse sequences with moderate bandwidths. However, they can be very accurate.

Iterative expansion starts with some pulse sequence $\mathbb{S}^{(0)}$ whose properties are close to those desired. The sequence is duplicated a small number of times Q . Each of the Q clones is subjected to a different ‘mutation’ which preserves its length. Two common transformations are to change the phase, or to permute an element from the beginning to the end. The Q mutations $\{\mathbb{S}_1^{(0)} \dots \mathbb{S}_Q^{(0)}\}$ are spliced together to form a sequence $\mathbb{S}^{(1)}$ which is Q times longer than $\mathbb{S}^{(0)}$:

$$\mathbb{S}^{(1)} = \mathbb{S}_1^{(0)} \mathbb{S}_2^{(0)} \dots \mathbb{S}_Q^{(0)} \quad (30)$$

The properties of the expansion depend on the mutations and their order. In many cases, it is possible to demonstrate that as long as $\mathbb{S}^{(0)}$ performs reasonably well, then $\mathbb{S}^{(1)}$ will perform better. Hence $\mathbb{S}^{(1)}$ can be reinserted in the machinery to derive a sequence $\mathbb{S}^{(2)}$ which performs better still:

$$\mathbb{S}^{(2)} = \mathbb{S}_1^{(1)} \mathbb{S}_2^{(1)} \dots \mathbb{S}_Q^{(1)} \quad (31)$$

If the original sequence $\mathbb{S}^{(0)}$ has n elements, the sequence $\mathbb{S}^{(M)}$ derived by M stages of expansion has nQ^M elements. Very long sequences with very high performance are rapidly built up.

Some examples of iterative expansion procedures are:

(1) *Cycles* are composite pulses whose overall rotation angles $\{\tilde{\alpha}, \tilde{\beta}, \tilde{\gamma}\}$ are all very close to zero.⁴⁰ They are used for broadband heteronuclear decoupling (see below). Cycles may be constructed by the following twofold iterative expansion.^{35, 36}

$$\mathbb{S}^{(m+1)} = [\mathbb{E}^{-1} \mathbb{S}^{(m)} \mathbb{E}]_{180} [\mathbb{E}^{-1} \mathbb{S}^{(m)} \mathbb{E}]_0 \quad (32)$$

where $\mathbb{E}$ is an element on the end of $\mathbb{S}^{(m)}$ with $\bar{\beta} \simeq \pi/2$, i.e. a nominal 90° pulse. This procedure consists of chaining together two cyclic permutations of the original sequence with different phases. Ideally, the sense of the cyclic permutation, and order of chaining, is reversed on alternate expansion stages, i.e.

$$\mathbb{S}^{(m+2)} = [\mathbb{E} \mathbb{S}^{(m+1)} \mathbb{E}^{-1}]_0 [\mathbb{E} \mathbb{S}^{(m+1)} \mathbb{E}^{-1}]_{180} \quad (33)$$

The accurate broadband cycle WALTZ-16⁴¹ was constructed roughly this way. It is given by

$$\begin{aligned} &270_{180} 360_{180} 180_{180} 270_{180} 90_{180} 180_{180} 360_{180} 180_{180} 270_{180} - \\ &270_{180} 360_{180} 180_{180} 270_{180} 90_{180} 180_{180} 360_{180} 180_{180} 270_{180} - \\ &270_{180} 360_{180} 180_{180} 270_{180} 90_{180} 180_{180} 360_{180} 180_{180} 270_{180} - \\ &270_{180} 360_{180} 180_{180} 270_{180} 90_{180} 180_{180} 360_{180} 180_{180} 270_{180} \end{aligned} \quad (34)$$

(2) *Compensated for rf field inhomogeneity 90° pulses* can be constructed by the following twofold expansion:⁴²

$$\mathbb{S}^{(m+1)} = [(\mathbb{S}^{(m)})^{\text{rev}}]_{270} [\mathbb{S}^{(m)}]_0 \quad (35)$$

The pulse sequence is written in inverse time order, shifted in phase by 270° , and placed next to the original sequence. For example, starting from $\mathbb{S}^{(0)} = 90_0$, we get $\mathbb{S}^{(1)} = 90_{270} 90_0$ and $90_{270} 90_{180} 90_{270} 90_0$, and so on. The longer the sequence, the better the rf compensation. This expansion produces variable rotation composite 90° pulses.

3. *Broadband 180° pulses* can be constructed by fivefold expansions, including^{33,34}

$$\mathbb{S}^{(m+1)} = [\mathbb{S}^{(m)}]_0 [\mathbb{S}^{(m)}]_{180} [\mathbb{S}^{(m)}]_{120} [\mathbb{S}^{(m)}]_{60} [\mathbb{S}^{(m)}]_{120} \quad (36)$$

This procedure is capable of compensating both resonance offset effects and rf inhomogeneity at the same time or, indeed, any form of pulse imperfection as long as it is reproducible and transforms properly under rf phase shifts. The highly compensated 25-element composite 180° pulse $180_0 180_0 180_{120} 180_{60} 180_{120} 180_0 180_0 180_{120} 180_{60} 180_{120} 180_{120} 180_{240} 180_{180} 180_{240} 180_{60} 180_{60} 180_{180} 180_{120} 180_{180} 180_{120} 180_{120} 180_{240} 180_{180} 180_{240}$ was constructed this way.^{33,34} This fivefold expansion procedure gives rise to variable rotation composite 180° pulses.

There is no space here to explain how these iterative expansion schemes work. An illuminating analysis has been given using the mathematical properties of repeated maps.³⁴

5.5 Global Pulse Sequence Compensation

Variable rotation composite pulses are generally shorter and have wider compensation bandwidths than constant rotation composite pulses. However, they must be used cautiously in experiments involving coherences, since they induce phase shifts according to Equation (25).

In weakly coupled spin systems, it is possible to balance the phase shift associated with one composite pulse by an equal and opposite phase shift associated with the following pulse. This requires that all pulses applied to a given spin species are

replaced simultaneously by variable rotation composite pulses of compatible construction.

A general method is to replace pulses with flip angle Θ and phase ϕ by composite pulses of the form $[\mathbb{L}]_\phi [\mathbb{R}]_{\phi-\Theta}$. Here $\mathbb{R}$ is a composite pulse with flip angle $\bar{\beta}^j \simeq \pi/2$ and $\mathbb{L}$ is a composite pulse with $\bar{\beta}^j \simeq -\pi/2$. The sequence $\mathbb{L}\mathbb{R}$ without any relative phase shift comprises a cycle. For brevity, the composite pulse pair $[\mathbb{L}]_\phi [\mathbb{R}]_\psi$ is denoted below by $\mathbb{L}_\phi \mathbb{R}_\psi$.

For offset compensation, suitable ‘left’ and ‘right’ sequences are

$$\left. \begin{aligned} \mathbb{L} &= 180_{180} 360_{180} 180_{180} 270_0 \\ \mathbb{R} &= 90_0 \end{aligned} \right\} \quad (37)$$

In this case the Euler angles of the sequence $\mathbb{L}_\phi \mathbb{R}_{\phi-\Theta}$ are

$$\left. \begin{aligned} \bar{\alpha}^j &\simeq \pi - \frac{\Delta\omega^j}{\Omega_1^0} - \phi \\ \bar{\beta}^j &\simeq \Theta \\ \bar{\gamma}^j &\simeq -\pi + \frac{\Delta\omega^j}{\Omega_1^0} + \phi - \Theta \end{aligned} \right\} \quad (38)$$

In weakly coupled spin systems, the ‘extra’ $\bar{\alpha}^j$ and $\bar{\gamma}^j$ rotations commute with the evolution in the interpulse delays. The $\bar{\gamma}^j$ rotation of one composite pulse can then be cancelled out by the $\bar{\alpha}^j$ rotation of the following composite pulse, providing the phase of the following pulse and all subsequent ones are shifted by $-\Theta$. These extra phase shifts must be accumulated iteratively throughout the sequence.

For example, a compensated version of the three-pulse sequence

$$(\Theta)_{\phi_1} - \tau - (\Xi)_{\phi_2} - \tau - (\Psi)_{\phi_3} - \dots \quad (39)$$

is

$$\begin{aligned} &\mathbb{L}_{\phi_1} \left[\mathbb{R}_{\phi_1 - \tau} - \mathbb{L}_{\phi_2} \left[\mathbb{R}_{\phi_2 - \tau} - \mathbb{L}_{\phi_3} \right. \right. \\ &\quad \left. \left. \mathbb{R}_{\phi_3} - \dots \right]_{-\Psi} \right]_{-\Xi} \end{aligned} \quad (40)$$

or, explicitly,

$$\begin{aligned} &\mathbb{L}_{\phi_1} \mathbb{R}_{\phi_1 - \Theta - \tau} - \mathbb{L}_{\phi_2 - \Theta} \mathbb{R}_{\phi_2 - \Theta - \Xi - \tau} \\ &\quad - \mathbb{L}_{\phi_3 - \Theta - \Xi} \mathbb{R}_{\phi_3 - \Theta - \Xi - \Psi} - \dots \end{aligned} \quad (41)$$

This procedure is readily extended to any number of pulses.

For compensation of rf inhomogeneity effects, the composite pulses $\mathbb{L} = 180_{300} 90_{180}$ and $\mathbb{R} = 90_0 180_{120}$ may be used instead.

The only defect in this scheme, apart from its complexity, is that the $\bar{\gamma}^j$ phase shift induced by the last composite pulse is left over at the end of the sequence. For resonance offset compensation this final phase shift is quite harmless. The frequency-dependent phase of the NMR signal is easily corrected by complex multiplication of the spectrum in the usual way. For rf field inhomogeneity, on the other hand, the final phase shift does lead to some signal loss by spatial dispersion of the magnetization vectors.

This type of global pulse sequence compensation has been demonstrated in multiple quantum NMR.^{7,16,17}

5.6 Nonbroadband Composite Pulses

Error compensation is only one mode of control of the nonlinear spin response. Several applications of composite pulses extend this concept.

5.6.1 Radiofrequency Field Selection

It is possible to design *narrowband* pulse sequences in which $\tilde{\beta}^j$ is very small except for a narrow range of rf field strengths Ω_1 . Such pulse sequences do not perturb the spin populations appreciably unless the rf field is close to the nominal value Ω_1^0 . It is possible to use this property as a means for *spatial selection* of the NMR signal.^{43–48} The pulse sequence is transmitted through an rf excitation coil with a well-defined spatial variation of rf field amplitude $\Omega_1(\mathbf{r})$. Only spins located in spatial regions with $\Omega_1 \simeq \Omega_1^0$ contribute strongly to the final NMR signal.

The most widely used composite pulses of this type have $\tilde{\beta}^j \simeq \pi$ over a narrow rf field range. Narrowband composite 180° pulses can be engineered by a number of methods, including the threefold iterative expansion scheme.⁴³

$$\mathbb{S}^{(m+1)} = [\mathbb{S}^{(m)}]_{240} [\mathbb{S}^{(m)}]_0 [\mathbb{S}^{(m)}]_{120} \quad (42)$$

The challenge is to find a pulse sequence with narrowband rf response which is not too adversely affected by resonance offsets. The performance of the composite 180° pulse 180₃₀180₂₀₅180₂₃₀180₈₅180₀180₈₅180₂₃₀180₂₀₅180₃₀⁴⁸ is illustrated in Figure 4(d). The narrowband selection of rf fields is maintained fairly well within the offset range $-0.3 \leq \Delta\omega^j / \Omega_1^0 \leq 0.3$.

5.6.2 Frequency-Selective Excitation

It is also possible to design pulse sequences with a tailored response with respect to the resonance offset $\Delta\omega^j$. For example, pulse sequences may be constructed with $\tilde{\beta}^j$ close to 90° over a wide frequency range, except for a narrow ‘hole’ close to $\Delta\omega^j = 0$. These *band-reject excitation* sequences can be used in the NMR of dilute solutions. Weak off-resonance solute NMR signals may be excited while avoiding the excitation of strong near-resonant signals from abundant solvent spins.

Sequences with this type of frequency-dependent excitation characteristic were available long before the first composite pulse appeared. However, insights from composite pulse design have allowed the construction of sequences which control the *phase* of the excited solute signals, as well as the amplitude. The angles $\tilde{\alpha}^j$ and $\tilde{\gamma}^j$ may be kept almost constant over the excitation bandwidth. Distortions associated with spectral phase gradients may thereby be avoided.^{49–53} The field is discussed further in *Water Signal Suppression in NMR of Biomolecules*.

5.6.3 Composite z Pulses

If rf field errors and resonance offset effects are small, the composite z pulse 90₂₇₀Θ₀90₀ produces an overall rotation defined by the angles $\{\tilde{\alpha}^j, \tilde{\beta}^j, \tilde{\gamma}^j\} \simeq \{\Theta, 0, 0\}$. This represents a rotation of the spin angular momenta through an angle Θ

about the z axis, as is easily verified by rotating any three-dimensional object, on the lines in Figure 5. In high magnetic field this z rotation is equivalent to a phase shift of all previous rf pulses by the same angle Θ. It is therefore possible to emulate the effect of arbitrary phase shifts on instruments equipped only for phase steps in multiples of 90°.^{54,55} This application was important before digital phase shifting became generally available on commercial instruments.

If the rf field is inhomogeneous in space, composite z pulses with very long nominal flip angle Θ produce a z rotation through a strongly spatially dependent angle $\tilde{\alpha}(\mathbf{r})$. The effect is similar to a *static field gradient pulse*, except that the inhomogeneity of the rf field, rather than that of the static magnetic field, is involved. Long composite z pulses of this type have been exploited to select signals arising from defined coherence transfer processes, as an alternative to phase cycling.⁵⁶ Time can be saved, and the suppression of undesirable signals improved.

6 COMPOSITE PULSES: SPIN COUPLINGS INCLUDED

In the applications discussed below, spin couplings are active during the composite pulse, and the dynamics of the spins cannot generally be visualized in three-dimensional space.

6.1 Heteronuclear Decoupling in Liquids

One of the most important applications of composite pulses is *broadband heteronuclear decoupling* in liquids (see *Decoupling Methods*). The NMR signals from one spin species (conventionally denoted as the S spins) is observed at the same time as a second spin species (conventionally the I spins) is irradiated with a long composite pulse sequence. Ideally the S spins evolve independent of the IS spin–spin coupling, even when there is a wide range of chemical shifts of the I spin species.

In isotropic liquids, it is usually a good approximation to ignore the *homonuclear* interactions between the irradiated I spins and take into account only the *heteronuclear* interactions, which are generally an order of magnitude larger. With this assumption, it has been shown that the problem of constructing a broadband decoupling sequence is formally equivalent to the construction of an accurate broadband *cycle* on *isolated* spins.^{35,36} This result, which is far from obvious, allows composite pulse sequences obtained by ignoring spin–spin couplings to be transplanted directly to this different context.

A wide range of broadband decoupling sequences have been constructed, usually by a combination of numerical optimization and iterative expansion. The popular sequence WALTZ-16 is given in equation (34).

For the highest possible resolution, sequences have been developed which also take the homonuclear J couplings into account.³⁷

6.2 Quadrupolar Compensation

In solids, spin interactions are large, and applied rf fields face serious competition. For example, quadrupole interactions of

spins $I \geq 1$ are generally much larger than achievable rf fields. Only for ^2H is the quadrupolar interaction sufficiently small that the concept of an 'ideal' rf pulse is at all realistic. But even in this case, the achievable rf field is generally comparable to the quadrupolar splitting. Composite pulses can then help make up for insufficient rf field strength.

6.2.1 Compensated Quadrupolar Echoes

The ^2H NMR signals of solid powders decay very rapidly because of the strong orientation dependence of the quadrupole splitting (see *Quadrupolar Nuclei in Solids; Deuterium NMR in Solids*). To obtain undistorted signals it is usually necessary to refocus the free induction decay by a *quadrupole echo*. This involves using two 90° pulses, 90° out of phase with each other, separated by a small delay τ_1 :

$$90_0 - \tau_1 - 90_{90} - \tau_2 - \text{Observe} \quad (43)$$

A spin echo is formed after an interval $\tau_2 \simeq \tau_1$ measured from the end of the second 90° pulse. Acquisition of NMR signals starting at the top of the spin echo gives high-fidelity ^2H powder spectra.

In a disordered sample, the quadrupole splitting in high field depends on the environment and molecular orientation of the nuclear site j and will be denoted here by $2\omega_Q^j$. If the rf field Ω_1 is comparable to $2\omega_Q^j$, the spin transformations induced by the 90° pulses are imperfect and the spin echo is distorted. This usually appears as weakened intensity at the edges of the ^2H powder peakshape. An example is the spectrum of d_5 -phenylalanine shown in Figure 7(a).

To correct this effect, each 90° pulse may be replaced by a composite 90° pulse. The composite pulse must take into account the competition between the rf field and the quadrupole coupling.

Construction of such composite pulses is far from easy. In principle, the density operator for a spin $I = 1$ evolves in an eight-dimensional space. However, there is one simplifying factor. In ^2H NMR, the chemical shifts are small. Although the frequencies of the two allowed transitions of the spin $I = 1$ nucleus are strongly orientation dependent, the *mean* frequency of the two transitions is always the same. It is possible to show that in this case, under certain constraints, quadrupole-compensated composite 90° pulses may be constructed by taking offset-compensated 180° pulses for isolated spins $\frac{1}{2}$, and dividing all pulse lengths by two.⁵⁷ The offset-compensated spin- $\frac{1}{2}$ 180° pulses must have the following properties:

1. Only 180° phase shifts must be involved.
2. Over the compensation bandwidth, the angles $\tilde{\alpha}^j$ and $\tilde{\gamma}^j$ must depend linearly on resonance offset $\Delta\omega^j/\Omega_1^0$.

The broadband spin- $\frac{1}{2}$ composite pulses $90_0 180_{180} 270_0$ and $90_0 270_{180} 180_0 360_{180} 180_0$ fulfil these conditions satisfactorily over the offset range $-1.0 \leq \Delta\omega^j/\Omega_1^0 \leq 1.0$ (the latter sequence being more accurate). On halving the pulse durations, the compensated quadrupole echo sequences

$$45_0 90_{180} 135_0 - \tau_1 - 45_{90} 90_{270} 135_{90} - \tau_2 - \text{Observe} \quad (44)$$

Figure 7 ^2H spectra of d_5 -phenylalanine, obtained using (a) the simple quadrupole echo pulse sequence [equation (43)], and (b) a composite pulse quadrupole echo sequence [equation (44)]. The rf field was rather weak in both cases, the duration of a nominal 90° pulse being $6.2 \mu\text{s}$. (Reproduced by permission of Elsevier from M. H. Levitt, *Prog. NMR Spectrosc.*, 1986, **18**, 61)

and

$$45_0 135_{180} 90_0 180_{180} 90_0 - \tau_1 - 45_{90} 135_{270} 90_0 180_{270} 90_0 - \tau_2 - \text{Observe} \quad (45)$$

are constructed. The improvement in spectral appearance produced by equation (44) is illustrated in Figure 7(b). Other sequences have also been suggested.^{7,57-61}

One problem of these quadrupole echo sequences is that they are rather long. Signal is lost if the coherence dephasing time T_2 of the deuterium spins is short due to molecular motion on a suitable timescale. This case is not uncommon. Composite pulse quadrupole echo formation is examined critically in Siminovitch et al.⁶¹

6.2.2 Compensated Population Inversion

Anisotropic molecular motion in solids is probed by measuring the orientation dependence of the ^2H spin-lattice relaxation time constant T_1 in a powder sample. A 180° pulse is applied to disturb the spin populations, a variable waiting period τ_{relax} is left, and a quadrupole echo sequence applied

to measure the NMR signal. Spectra are taken for a range of values of τ_{relax} . The partially relaxed quadrupole lineshapes may be analyzed to obtain the dependence of T_1 on sample orientation.

This method requires proper performance of the first 180° pulse. However, a 180° pulse applied to spins $I = 1$ is very sensitive to the quadrupole splitting.⁷ The transformed z angular momentum R_{zz}^J is below -0.8 only if the quadrupole splitting $2\omega_Q^J$ is less than around $1.2\Omega_1^0$, where Ω_1^0 is the rf field strength. To get a reasonable inversion of a 150 kHz wide ^2H powder pattern, the rf field must be sufficiently strong that the 90° pulse duration is less than $2\mu\text{s}$.

Broadband population inversion of ^2H spins may be achieved with much weaker rf fields by using composite 180° pulses. The sequence $45_0 90_{180} 135_0 45_{90} 90_{270} 135_{90} 45_0 90_{180} 135_0$ allows inversion of a 150 kHz quadrupole powder pattern using an rf field of only $\Omega_1^0/2\pi = 37.5\text{ kHz}$, which corresponds to a 90° pulse length of $6.5\mu\text{s}$.⁷ Longer sequences with flatter inversion profiles have also been designed.⁶⁰ Improved performance is attainable even with the simple composite pulse $90_0 90_{90} 90_0$.⁶²

6.3 Dipolar Compensation

Nuclear spin dynamics are extremely complicated in the presence of extended dipolar coupling networks, as is typical for abundant spin species in solids. Compensation of these effects is even more challenging than for quadrupole couplings.

6.3.1 Compensation of Homonuclear Dipolar Couplings

Coherent averaging theory (Section 5.4.3) provides a general framework for compensation of undesirable interactions, using only the rotational symmetry of those interactions. This has allowed the development of composite pulses such as $45_0 180_{90} 90_{180} 180_{90} 45_0$, a broadband 180° pulse compensated for dipolar or quadrupolar interactions.²⁵ Improved population inversion has been demonstrated for networks of coupled protons in solids as well for quadrupolar spins. Composite pulses have also been constructed for NMR imaging in solids.⁶³

The theory of composite pulses in dipolar-coupled systems overlaps strongly with the theory of line-narrowing multiple-pulse sequences (see *Line Narrowing Methods in Solids*). Indeed, many of the same pulse sequences can be used. The composite pulse $90_0 180_{90} 90_{180} 180_{90}$ is a dipolar-compensated 180° pulse as well as a segment of the line-narrowing sequence BLEW-12.⁶⁴

6.3.2 Heteronuclear Decoupling in Anisotropic Systems

Heteronuclear decoupling in solids and liquid crystals is far more difficult than in isotropic liquids, because both homonuclear and heteronuclear interactions are generally large. Despite the theoretical difficulties, progress has been made towards the goal of low-power broadband decoupling in anisotropic systems.^{65–67} One promising sequence is

$$[\mathbb{E}]_{90}[\mathbb{E}]_{10}[\mathbb{E}]_{90}[\mathbb{E}]_{10}[\mathbb{E}]_{90}[\mathbb{E}]_{10}[\mathbb{E}]_{270}[\mathbb{E}]_{10}[\mathbb{E}]_{270} \\ \times [\mathbb{E}]_{10}[\mathbb{E}]_{270}[\mathbb{E}]_{10} \quad (46)$$

where each element $\mathbb{E}$ is a constant rotation offset-compensated composite 90° pulse, $\mathbb{E} = 385_0 320_{180} 25_0$. Improved heteronuclear decoupling in liquid crystals and magic angle spinning solids has been demonstrated.^{65–67}

6.4 Coherence Propagation through J-Coupling Networks

Another important application of composite pulse sequences is to propagate spin coherence through the J coupling networks of molecules in isotropic solution. In conjunction with two-dimensional spectroscopy, such sequences are commonly used as an aid to spectral assignment. The method is generally known under the names total coherence transfer spectroscopy (TOCSY) or homonuclear Hartmann Hahn (HOHAHA) spectroscopy. A similar application is when long composite pulse sequences are used to implement coherence transfer through transverse cross relaxation—an experiment generally known under the (misleading) name rotating frame nuclear Overhauser effect spectroscopy (ROESY) (see *ROESY*).

The theory of composite pulse sequences in this context is challenging. In particular, analysis of the relaxation during long composite pulse trains has required theoretical innovations.⁶⁸ Some of the popular pulse sequences are discussed in *TOCSY in ROESY and ROESY in TOCSY*.

7 COMPENSATION FOR COUPLING VARIATIONS

In the intervals between rf pulses, evolution of the spin system takes place under the influence of chemical shifts, quadrupole couplings and spin–spin coupling terms. Many pulse sequences include fixed delays which should be matched to certain coupling constants for proper operation. For example, in the NMR of isotropic liquids, pulse sequences commonly include a fixed delay $\tau_J = 1/(2J)$ to allow exchange of antiphase and in-phase coherences under the influence of the J coupling. Often 180° pulses are inserted in the middle of the delay to suppress chemical shift evolution. A typical example is the INEPT sequence (see *INEPT*) for polarization transfer from I spins to S spins.

$$I : 90_0 - \tau_J/2 - 180_0 - \tau_J/2 - 90_{90} \\ S : \quad \quad \quad 180_0 \quad \quad \quad 90_0 \text{ (Acquire signal)}$$

Polarization transfer is only optimal if the heteronuclear J coupling really does correspond to the set delay τ_J . In real samples there is a spread of J values leading to a loss of polarization transfer for some sites.

This situation resembles that of a single rf pulse in an inhomogeneous rf field, where the chosen pulse duration corresponds to a nominal rf field actually experienced only by a minority of spins. In that case the spread of nutation angles is compensated by making composite pulses. Similarly, the spread of J couplings in polarization transfer experiments is compensated by building composite INEPT analogs.

Several research groups have investigated this.^{70,71} One general procedure is explained,⁷⁰ where the following compensated sequence is demonstrated:

$$I : 90_0 - \tau_J/2 - 180_0 - \tau_J/2 - 120_{90} - \tau_J/2 - 180_0 - \tau_J/2 - 30_{90} \\ S : \quad \quad \quad 180_0 \quad \quad \quad 180_0 \quad \quad \quad 90_{90} \text{ (acquire)}$$

Although far from obvious, this composite INEPT sequence is an analog of the rf-compensated composite 90° pulse 90_0180_{120} . The polarization transfer is less sensitive than ordinary INEPT to variations in the values of the J couplings. It has also been shown that in some many-spin systems, certain J -compensated INEPT sequences can induce more coherence transfer than ordinary INEPT, even when the latter is at its optimum. For example, for $^1\text{H} \rightarrow ^{13}\text{C}$ polarization transfer in CH_3 groups, around 33% more polarization transfer is achieved by certain composite INEPT sequences compared to ordinary INEPT.⁷⁰

This is only one example of a large range of composite pulse sequences compensated for variations in coupling constants. Some others are as follows:

1. Hartmann–Hahn cross polarization experiments in liquids have been compensated for variations in J values by making an analogy with the composite pulse $90_{90}180_090_{90}$.⁷²
2. Double quantum excitation sequences in liquid crystal NMR have been compensated for a range of dipolar coupling constants.⁷³
3. Bilinear rotation sandwiches have been compensated for J coupling variations in a whole palette of intriguing pulse schemes.^{70,71,74–81}
4. Sequences for exciting quadrupolar order in solids and liquid crystals (Jeener–Broekaert sequences) have been compensated for a spread in quadrupolar coupling constants caused by orientational inhomogeneity.⁸²
5. Excitation of spin magnetization in nuclear quadrupole resonance (NQR) (see *Quadrupolar Interactions*) has been compensated for the spread of effective nutation fields caused by the orientational distribution in a powder sample.^{2,3}

1 INTRODUCTION

Combined rotation and multiple pulse spectroscopy (CRAMPS)¹ is one means of using transient techniques in NMR to achieve liquid-like high-resolution NMR spectra of hydrogen and fluorine in solids. Herein will be described the basic ideas leading to the achievement of this resolution. The background required is that obtained by exposure to an undergraduate physical chemistry course, with a smattering of perturbation theory included. There will necessarily be some overlap between the description below, and other articles in this Encyclopedia. Cross references to pertinent subjects are given at the end of the article.

Of all the elements encountered by medical, biological, chemical, and physical scientists, hydrogen is perhaps the most common. The NMR-active nuclide, ^1H , is 99.98% abundant, and the magnetic moment is exceeded in magnitude only by the nonnaturally occurring tritium, ^3H . ^1H was the first nucleus for which NMR was reported.^{2,3} Because of the magnitude of its magnetic moment, and its natural abundance, hydrogen is the most easily detected nucleus commonly encountered in NMR. It is routinely used for qualitative and quantitative analysis of organic molecules in the liquid state.

Chemical shifts of hydrogen in organic molecules in solution commonly have a range of about 15 ppm of the resonance frequency. For example, protons in common organic molecules in a spectrometer operating at 500 MHz for ^1H will exhibit a chemical shift range of about $15 \times 500 = 7500$ Hz. Scalar couplings to other hydrogen atoms and to carbon atoms are characteristically around 100 Hz. Resolution in commercial liquid state spectrometers is of order of a few tens of hertz, so hydrogen NMR on molecules in the liquid state supplies an easily detectable, well resolved, and sensitive fingerprint for routine analysis.

It was thus initially disappointing that under a single resonant excitation such as was used on liquids, NMR spectra of hydrogen in solids such as ice, or high molecular weight proteins, are broad and featureless. The linewidths are about 15 kHz, an example being given for hydrogen in adipic acid in Figure 1(a).

Exactly those qualities which make ^1H such a valuable label for liquid state NMR destroy the resolution of the NMR spectrum of hydrogen in solids. The reasons are physically

Figure 1 Comparison of NMR spectra taken under: (a) single pulse excitation; (b) MAS at 6 kHz; (c) MAS at 8 kHz; (d) MAS at 11 kHz; (e, f) CRAMPS. (Courtesy of Gary Maciel)

obvious. ^1H is a nucleus with relatively high abundance and large magnetic moment. In a static field it behaves as a magnet, producing a magnetic field with the familiar symmetry exhibited by iron filings aligning in the neighborhood of a bar magnet. In the solid state, each hydrogen atom will be exposed not only to the static field of the magnet used for NMR, but also to the sum of the 'dipolar' fields of all other abundantly present protons in the sample. The result is that the resonance frequency of any hydrogen atom in the sample is homogeneously broadened by the effect of the dipolar fields. In addition, there is NMR line broadening in a motionless solid due to the nonspherical symmetry of the surrounding bonding electronic cloud, i.e. due to 'shielding anisotropies'. CRAMPS was developed to attenuate these two major sources of line broadening such that liquid-like NMR spectra of ^1H and ^{19}F in solids are achieved in favorable cases.

CRAMPS involves manipulations common to NMR of both liquids and solids. These cause the system under observation to vary in time such that chemical shifts become more resolved. Other interactions, e.g. dc field inhomogeneities in liquids, are averaged to small values. A critical fact here is that all observables depend on variables in both real space (r, θ, ϕ), and spin space (components of spin angular momentum, $\hat{I}_k$, $k = x, y, z$) (see *Internal Spin Interactions and Rotations in Solids*). The manipulations used selectively to attenuate

internal interactions which cause a loss of resolution therefore include the following:

1. Sample motion in the laboratory makes θ and ϕ time-dependent. For liquids, spinning rates are roughly 100 Hz. Solids are commonly spun 100 times faster.
2. Radiofrequency (rf) pulsing makes the components of the spin angular momentum operators ($\hat{I}_x$, $\hat{I}_y$, and $\hat{I}_z$) time-dependent.

Rotations in real space,^{4,5} e.g. magic angle spinning, accomplish what molecular tumbling of molecules in the liquid state does for the shielding anisotropy; namely, it averages the anisotropic shielding to its isotropic, or average, value.

Radiofrequency pulses may be thought of as rotating magnetic moments in 'spin space'. We may therefore think of the combined rotation and multiple pulse technique as using rotations in both 'spin space' and in the real space of the laboratory. As understood early on⁶⁻⁸ and shown below, rotations in spin space via rf pulses can be arranged to average local dipolar fields, and the resulting NMR line broadening to values smaller than differences in chemical shifts.

An example of the CRAMPS spectrum⁹ of hydrogen in adipic acid, $\text{HOOC}(\text{CH}_2)_4\text{COOH}$, is shown in Figure 1(e) and (f). Figure 1(b)–(d) show spectra of the static sample under a single pulse excitation, roughly 40 kHz wide, and the spectrum of the sample under magic angle spinning (see below) at frequencies between 6 and 11 kHz. It can be seen that the resolution between the top and the bottom spectrum has increased under CRAMPS by a factor of roughly 600.

In order to illustrate how the experiment works, we first consider how the physical rotation of solid samples narrows the broadening effect of shielding anisotropies. Then we consider how sequences of rf pulses narrow dipolar broadening.

2 ROTATIONS IN REAL SPACE

The most common motion familiar to the NMR spectroscopist working in liquids is that of simply spinning the NMR tube containing the liquid sample about an axis perpendicular to the static field. This partially averages dc field inhomogeneities over the sample volume and improves resolution. Rotation of a liquid at the magic angle further narrows the lines of liquids (see *Magnetic Susceptibility and High Resolution NMR of Liquids and Solids*). The manner in which this works might be perhaps understood by a related example. An individual enthusiastic about the game of football, but without much background in mechanics, constructs a sheet metal wind vane, cut into the shape of an American football. The dynamic balance of this particular device is such that instead of pointing to indicate wind direction, it rotates as the wind blows. For rotation too fast for the eye to follow, the football shaped device, being a thin slice the width of the metal when viewed end-on, and a football shaped object when viewed perpendicular to the surface, seems on average to become something smaller than a football, and something larger than a line. On average, it seems that a circular object is seen. Glancing at the wind vane in a high wind, the builder rapidly blinks at this dysfunction of the device. In doing so, the blinking is unwittingly done in concert with the rotation period of the wind vane, and for an instant, instead of the football shaped wind vane, a very narrow line is seen! Each time the eyes were opened, a

stroboscopic observation was made of the wind vane viewed head-on.

Following the football analogy, consider the symmetry of the bonding electron cloud about an NMR active ^{13}C in a CO_2 molecule, $\text{O}=\text{C}=\text{O}$. Clearly this cloud is roughly football shaped. This bonding electron cloud may be thought to circulate in reaction to the imposition of a static magnetic field, producing a 'shielding field'. The details of the circulation, and thus the shielding field, described in terms of a 'shielding ellipsoid' σ , will be different when the static field is perpendicular to the unique axis of the football than when parallel to it. In fact the shielding field produces an NMR line at $\delta = -90$, i.e. 90 ppm upfield (down frequency; shielded) with respect to ^{13}C in tetramethylsilane (TMS), when the static field is parallel to the unique axis. With the field perpendicular to the unique axis, δ is 245 ppm deshielded with respect to ^{13}C in TMS. In the liquid state, the NMR spectrum of ^{13}C in CO_2 is a narrow line 133 ppm deshielded from TMS. Sufficiently rapid isotropic (random in space) tumbling of the molecule in the liquid results in this football shaped object becoming spherical as viewed by the eye of NMR; the anisotropic shielding is averaged to its isotropic value, which is the average of the three principal axes of the shielding ellipsoid. Note that $133 = (245 + 245 - 90)/3$; the isotropic value of the chemical shift of ^{13}C in CO_2 in the liquid is the average of the values with the dc field along the x , y , and z axes of the shielding ellipsoid.

When the NMR spectrum of carbon dioxide is measured in the powdered, solid state, as dry ice, molecular tumbling is absent. In this case each crystallite contributes an NMR line between 245 ppm and -90 ppm, depending upon the orientation of the shielding ellipsoid in the crystallite to the static field. The total spectrum appears as the 'powder pattern' shown in Figure 2. The weighting of intensity on the high frequency side, corresponding to the static field in the (x, y) plane of the shielding ellipsoid, corresponds to the fact that it is more likely that a given crystallite will have the static field near the (x, y) plane of the shielding ellipsoid than uniquely along the axis of rotation.

The resonance frequency depends on the orientation of the shielding ellipsoid with respect to the static magnetic field, specified by angles θ and ϕ , as shown in Figure 3, and on the asymmetry of the ellipsoid. This asymmetry is uniquely specified by the magnitudes of its three principal axes in ppm

Figure 2 NMR of ^{13}C in powdered solid CO_2 . Illustration of shielding anisotropy for an axially symmetric shielding environment. (Courtesy of Anita Orendt)

Figure 3 Relationship between the principal axes of the shielding ellipsoid and the laboratory coordinate system; definitions of θ and ϕ

of the resonance frequency, denoted by σ_{xx} , σ_{yy} , and σ_{zz} , or in terms of linear combinations of these which more clearly exhibit the symmetry properties. The combinations are

- (a) the average of the magnitudes of the three principal axes, σ_{iso} , the isotropic shielding, which is that quantity observed in NMR of liquids;
- (b) the anisotropy ζ , equal to the difference between σ_{zz} and σ_{iso} ;
- (c) the asymmetry η , proportional to the difference in the x and y components.

We note that a similar ellipsoid describes the anisotropy of the dipolar interaction $\mathbf{D}$ between two nuclei, but in this case the interaction is axially symmetric, $D_{xx} = D_{yy}$, so the asymmetry for the dipolar interaction is zero.

The resonance frequency of a shielding ellipsoid oriented at θ , ϕ with respect to $\mathbf{B}_0$, and with symmetry specified by σ_{iso} , ζ , and η is given by

$$\omega(\theta, \phi, \sigma_{iso}, \zeta, \eta) = \omega_0 \{ \sigma_{iso} + \zeta \left[\frac{1}{2} (3 \cos^2 \theta - 1) + \frac{1}{2} \eta \sin 2\theta \cos 2\phi \right] \} \quad (1)$$

When the sample is set in motion, e.g. by random molecular tumbling, as would take place when the sample is heated to the liquid state, or by sonic agitation of the finely divided solid in a suitable liquid (see *Ultrasonic Irradiation and NMR*), or by the experimenter about an axis oriented at an angle β to the static field, and at a frequency that is fast compared with the spectral width $\omega_0(\sigma_{xx} - \sigma_{zz})$, it may be shown (see *Internal Spin Interactions and Rotations in Solids*) that the averaged frequency becomes only a function of the isotropic chemical shift σ_{iso} , the anisotropy ζ , and the angle β between the spinning axis and the field. This relationship is given by

$$\omega(\omega_0, \beta, \sigma_{iso}, \zeta) = \omega_0 [\sigma_{iso} + \frac{1}{2} \zeta (3 \cos^2 \beta - 1)] \quad (2)$$

The terms in η disappear if the sample is spun rapidly enough, or contribute to sidebands if the spinning rate is smaller than the shielding spectral width. Clearly at the ‘magic’ angle $\beta = \arccos(\frac{1}{3})^{1/2}$, only the isotropic value remains; the

spinning has achieved a liquid-like spectrum by averaging the anisotropic information to zero.

It was recognized early on that MAS could also average the dipolar broadening to zero. However, since all nuclei in a sample rich in protons are connected to all others via the through-space dipolar interactions, it is necessary to spin fast compared with the dipolar linewidth to achieve effective narrowing. This means spinning fast compared with 15 kHz, or fast compared with roughly 10^6 rev min⁻¹. Such spinning speeds are not easily achieved, but have been realized in homemade spectrometers with easily machineable polyimide resins,¹⁰ and are also now available in commercial spectrometers making use of high-precision cylindrical ceramic rotors. A comparison of narrowing under ultrafast MAS and the use of CRAMPS has been made,¹¹ with the conclusion that one would like to have access to both techniques, depending upon the sample. Furthermore, there are spin dynamics containing added information which one may perform using CRAMPS which are not available within the expedient of high speed spinning.

We now consider how manipulating the nuclear spin system with rf pulses averages the dipolar interactions to values smaller than differences in chemical shifts. To do so, we use the background developed in the article *Echoes in Solids*.

3 ROTATIONS IN SPIN SPACE

All spectroscopy experiments implicitly or explicitly involve solutions of the time dependent Schrödinger equation. We have implicitly invoked one such solution in discussing MAS, above. An understanding of NMR appropriate to the level of this Encyclopedia involves at least a rudimentary knowledge of the solutions of this equation in the density operator formulation. Fortunately there are texts for students at both the entry level^{12,13} and advanced levels,^{14–16} presenting both these pictures. As a basis for understanding the multiple pulse portion of the CRAMPS experiment, I briefly summarize the results of selective averaging theory on first the shielding interaction, and then the dipolar interaction. Let us start in the rotating frame of the Zeeman interaction, the frame in the real world in which NMR signals are detected after demodulation removes the carrier frequency from the information content of the signal. In the rotating frame, the principal effective magnetic fields which cause a proton to resonate for detection by NMR are: (a) the externally applied rf field, $\mathbf{B}_1$, and (b) the sample-supplied, or internal average, of the dipolar fields of all other protons, $\mathbf{B}_D$. A smaller perturbation is that of the anisotropic shielding field associated with the reaction to electrons in the environment of the hydrogen nucleus of the static external field.

With each field is associated an energy, and a quantum mechanical energy operator $\hat{\mathcal{H}}$. Thus the energy operator in the rotating frame is given by

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}_{rf} + \hat{\mathcal{H}}_{int} \quad (3)$$

where the magnitude of $\hat{\mathcal{H}}_{rf}$ for purposes of solid state experiments is about 5 mT. The magnitude of $\hat{\mathcal{H}}_{int}$ is never greater than a few tenths of a millitesla in the case discussed here—that of homonuclear dipolar coupling. The equation of

motion of the system is then given by the solution to the time dependent Schrödinger equation in the density matrix formulation:

$$i\frac{d\hat{\rho}}{dt} = [\hat{\mathcal{H}}, \hat{\rho}] \quad (4)$$

Here, $\hat{\mathcal{H}}$ is the sum of the rf and internal interactions, as specified in equation (3), $\hat{\rho}$ is the density operator, specified by the wavefunction $|\psi\rangle$, as $|\psi\rangle\langle\psi|$ in Dirac bracket notation. The average values of observables, e.g. $\langle\hat{I}_y(t)\rangle$, the free induction decay detected along the y phase in the rotating frame, are given by

$$\langle\hat{I}_y(t)\rangle = \text{Tr} [\hat{\rho}(t)\hat{I}_y] \quad (5)$$

With the interactions separated in magnitude in this manner, it makes sense to treat $\hat{\mathcal{H}}_{\text{int}}$ as a perturbation on $\hat{\mathcal{H}}_{\text{rf}}$. Recall that the transformation to the frame of the Zeeman interaction (the rotating frame) simplifies the description of a nuclear spin in the presence of other interactions; e.g. the oscillating on-resonance rf field becomes static in the rotating frame. Similarly, transformation to the frame of the now largest interaction, the rf field, further simplifies the description of the system. The transformation to the frame of the rf field is accomplished by the relationships

$$\hat{\rho} = \hat{U}_{\text{rf}}\hat{\rho}\hat{U}_{\text{rf}}^{-1} \quad (6)$$

$$i\frac{d\hat{U}_{\text{rf}}}{dt} = \hat{\mathcal{H}}_{\text{rf}}\hat{U}_{\text{rf}} \quad (7)$$

$$\hat{U}_{\text{rf}}(0, 0) \equiv \hat{U}_{\text{rf}}(t = 0) = \hat{1} \quad (8)$$

$$\hat{\mathcal{H}}_{\text{int}}(t) = \hat{U}_{\text{rf}}^{-1}(t, 0)\hat{\mathcal{H}}_{\text{int}}\hat{U}_{\text{rf}} \quad (9)$$

As mentioned above, the notation $\hat{U}(t, 0)$ is a formal way of saying that the propagator $\hat{U}$ drives the system from time 0 to time t . An explicit operational form of $\hat{U}$ will be given below; for now, accept it as that quantity causing the system to proceed in time, with physical origin in the time-dependent sequence of rf pulses, and the internal interactions as affected by these pulses. The result,

$$i\frac{d\hat{\rho}}{dt} = [\hat{\mathcal{H}}_{\text{int}}, \hat{\rho}] \quad (\text{energy in units of frequency}) \quad (10)$$

is the equation of motion in the frame of the rf field. Now, in the same spirit with which we used the interaction $\hat{\mathcal{H}}$ to transform itself out of the equation of motion [this interaction does not appear in equation (10)] we use the interaction $\hat{\mathcal{H}}_{\text{int}}$ to make another transformation which transforms $\hat{\mathcal{H}}_{\text{int}}$ out of the equation:

$$\hat{\rho} = \hat{U}_{\text{int}}(t, 0)\hat{\rho}\hat{U}_{\text{int}}^{-1}(t, 0) \quad (11)$$

$$i\frac{d\hat{U}_{\text{int}}}{dt} = \hat{\mathcal{H}}_{\text{int}}\hat{U}_{\text{int}} \quad (12)$$

$$\hat{U}_{\text{int}}(0, 0) = 1 \quad (13)$$

Thus $\hat{\rho}$ is replaced by $\hat{\hat{\rho}}$, $\hat{\rho}$ is replaced by $\hat{\hat{\rho}}$, $\hat{U}_{\text{rf}}$ is replaced by $\hat{U}_{\text{int}}$, etc. As shown by equation (14), the system in this frame is static; that is,

$$i\frac{d\hat{\hat{\rho}}}{dt} = [0, \hat{\hat{\rho}}] = 0 \quad (14)$$

We formally identify this static system with the system at time zero; $\hat{\hat{\rho}}$ then becomes identical to $\hat{\rho}(0)$. In this perturbation picture, with $\hat{\mathcal{H}}_{\text{int}}$ being a perturbation on $\hat{\mathcal{H}}_{\text{rf}}$, the motion of the system, is then described by

$$\hat{\rho}(t) = \hat{U}_{\text{rf}}(t, 0)\hat{U}_{\text{int}}(t, 0)\hat{\rho}(0)\hat{U}_{\text{int}}^{-1}(t, 0)\hat{U}_{\text{rf}}^{-1}(t, 0) \quad (15)$$

4 ECHOES AND THE AVERAGE HAMILTONIAN

Before discussing the operational forms of the propagators $\hat{U}$ explicitly, let us examine equation (15) more closely. It is clear that if both $\hat{U}_{\text{rf}}(t_c, 0)$ and $\hat{U}_{\text{int}}(t_c, 0)$ are unity at some particular time t_c , then at this special time it appears that the system has simply not changed, i.e. equations (4) and (15) at time t_c tell us that the value of any observable at this time is the value of that observable's operator at time zero; at time t_c , $\hat{\rho}(t_c) = \hat{\rho}(0)$. There is therefore an enormous simplicity in the behavior of the system which the experimenter may accomplish with proper arrangements of rf pulses, since both $\hat{U}_{\text{rf}}$ and $\hat{U}_{\text{int}}$ depend upon $\hat{\mathcal{H}}_{\text{rf}}$ —the rf pulses which we supply! The fields (5 MT) generated by the rf pulses are much larger than the 'internal fields' due to dipolar and shielding interactions (<0.3 MT). Therefore, as long as $\hat{U}_{\text{rf}}$ operates for times that are short compared with times in which $\hat{U}_{\text{int}}$ affects the system, its motion is predominantly controlled by $\hat{U}_{\text{rf}}$. Then if the sequence of rf pulses generating $\hat{U}_{\text{rf}}(t_c, 0)$ returns the system to its initial state, $\hat{U}_{\text{rf}}(t_c, 0)$ is formally equal to unity, a result inferred from physics rather than mathematics. Examples of such pulse sequences are easily imagined if the physics is kept clearly in mind. For example, the sequence $(\tau, 180^\circ_x, 2\tau, 180^\circ_x, \tau)$ results in a rotation by 2π about the x axis, leaving the system invariant at cycle time t_c equal to time 4τ . The sequence $(\tau, 90^\circ_y, \tau, 90^\circ_x, 2\tau, 90^\circ_{-x}, \tau, 90^\circ_{-y}, \tau)$ has phase alternated pairs of pulses which cancel against each other (the y pulse cancels against the $-y$ pulse, and similarly for x) and leaves the system invariant at a cycle time t_c of 6τ . This phase alternated sequence (for each x , a $-x$, and for each y a $-y$) is a variant of the solid echo sequence¹⁷⁻¹⁹ which became famous as the WAHUA (after John Waugh, Lee Huber, and Ulrich Haeberlen) sequence. Such sequences are said to be cyclic. If these groups of pulses are repeated periodically, they are both cyclic and periodic (see *Average Hamiltonian Theory*). As long as $\hat{U}_{\text{rf}}(nt_c, 0)$ is the dominant propagator, in the 'windows' between these groups of pulses, the system will behave as if it is not moving in time. The

situation is quite analogous to the observation of the spinning football shaped object by the blinking football fan. If the blinking is done in concert with the rotation at such a time that the object is viewed head-on, i.e. when it appears as a thin line, then only a thin line will be seen at all times of observation.

A closer look at equation (15), however, clearly indicates that as time progresses, $\hat{U}_{\text{int}}(nt_c, 0)$ begins to affect the motion of the system. Stroboscopic observation as time progresses, in the windows nt_c , will reveal some motion due to $\hat{U}_{\text{int}}(nt_c, 0)$. Now this propagator, $\hat{U}_{\text{int}}(nt_c, 0)$, is determined by $\hat{\mathcal{H}}_{\text{int}}$. The interaction $\hat{\mathcal{H}}_{\text{int}}$ is the sum of $\hat{\mathcal{H}}_{\text{D}}$ and $\hat{\mathcal{H}}_{\text{CS}}$, the dipolar and shielding interactions as manipulated by the rf pulses. If somehow the dipolar interaction (but not the shielding interaction) can be selectively set in motion so that its time average at times nt_c is zero, the remaining information in the windows of the stroboscopic observation will be the shielding. This is exactly what multiple pulse homonuclear decoupling attempts to accomplish. To see how this works, one needs an explicitly operational form for the internal propagator $\hat{U}_{\text{int}}(nt_c, 0)$. The form is illustrated by the spin echo sequence $(\tau, 180^\circ_y, \tau, 180^\circ_y, \tau)$. In the spin echo sequence, we take the internal Hamiltonian to represent any interaction proportional to the operator $\hat{I}_z$: e.g. shielding, resonance offset, static field inhomogeneities, and scalar couplings to unlike nuclei. Homonuclear dipolar coupling, as shown below, is not proportional to $\hat{I}_z$.

When we manipulate $\hat{\mathcal{H}}_{\text{int}}$ by cyclic and periodic sequences of rf pulses (meaning $\hat{U}_{\text{rf}}(t_c, 0)$ is unity) the form of the propagator $\hat{U}_{\text{int}}$ becomes an exponential,²⁰ with the leading term in the result, stroboscopically observed at cycle times nt_c , given by

$$\begin{aligned} \hat{\rho}(nt_c) &= \hat{U}_{\text{int}}(t_c, 0) \hat{\rho}(0) \hat{U}_{\text{int}}^{-1}(t_c, 0) \\ &= \exp(-i \hat{\mathcal{H}}_{\text{int}}^{(0)} nt_c) \hat{\rho}(0) \exp(i \hat{\mathcal{H}}_{\text{int}}^{(0)} nt_c) \end{aligned} \quad (16)$$

Here, $\hat{\mathcal{H}}_{\text{int}}^{(0)}$, which is equal to the integral over a cycle of the internal Hamiltonian as manipulated in time by the rf pulses,

$$\hat{\mathcal{H}}_{\text{int}}^{(0)} = \frac{1}{t_c} \int_0^{t_c} \hat{\mathcal{H}}_{\text{int}} dt \quad (17)$$

may be interpreted as the time average of this manipulated internal Hamiltonian. The manner of manipulation of $\hat{\mathcal{H}}_{\text{int}}$ is given by:

$$\hat{\mathcal{H}}_{\text{int}}(t) = \hat{U}_{\text{rf}}^{-1}(t, 0) \hat{\mathcal{H}}_{\text{int}} \hat{U}_{\text{rf}}(t, 0) \quad (18)$$

$\hat{\mathcal{H}}_{\text{int}}(t)$ is the instantaneous value of the internal Hamiltonian as determined by the rf pulses. $\hat{U}_{\text{rf}}(t, 0)$ is the propagation operator due to the rf pulses from time zero to time t . For n time intervals $\Delta 1$, followed by $\Delta 2, \dots$, followed by Δn , $\hat{U}_{\text{rf}}$ is clearly the propagator during interval $\Delta 1$, followed by the propagator over $\Delta 2, \dots$, as shown by

$$\hat{U}_{\text{rf}}(t, 0) = \hat{U}_{\text{rf}}(\Delta n) \cdots \hat{U}_{\text{rf}}(\Delta 1) \quad (19)$$

The inverse of this product of matrix operators is given by

$$\hat{U}_{\text{rf}}^{-1}(t, 0) = \hat{U}_{\text{rf}}^{-1}(\Delta 1) \cdots \hat{U}_{\text{rf}}^{-1}(\Delta n) \quad (20)$$

The physical meaning of the exponentials in equation (16) can always be expressed as a product of rotations in spin space acting on components of angular momentum operators. For example, consider the rf pulse sequence with perfect delta function pulses $(\tau, 180^\circ_y, 2\tau, 180^\circ_y, \delta)$ shown in Figure 4. This sequence is used to produce $\hat{\mathcal{H}}_{\text{rf}}$, and thus $\hat{U}_{\text{rf}}$, equal to $\exp(-i \int \hat{\mathcal{H}}_{\text{rf}} dt)$, as indicated in Figure 4.

At times $0 < t < \tau$, when the rf Hamiltonian is zero, $\hat{U}_{\text{rf}}(t, 0)$ takes the form $e^0 = 1$, and in this time interval the value of $\hat{I}_z$ as manipulated by the rf pulse sequence in Figure 4 is given by equation (18). We may physically identify $\hat{U}_{\text{int}}(0 < t < \tau)$ as given in equation (18) with a rotation $\hat{R}$, of unity, performed on $\hat{I}_z$, symbolized by $\hat{R}\hat{I}_z = 1\hat{I}_z$. At time $t = \tau$, the rf Hamiltonian corresponding to the delta function pulse becomes an infinitely fast 180° rotation about the y axis. $\hat{U}_{\text{rf}}(t = \tau) = \exp(i\pi\hat{I}_y)$, and the physical result is a 180°_y rotation $\hat{R}_{180y}$, which sends the operator $\hat{I}_z$ into the operator $-\hat{I}_z$: $\hat{R}_{180y}\hat{I}_z = -\hat{I}_z$. For $\tau < t < 2\tau$ the rf again is zero, and $\hat{U}_{\text{rf}}$ is unity. At $t = 3\tau$, another 180°_y takes place. Under this sequence, therefore, with the spin portion of $\hat{\mathcal{H}}_{\text{int}}$ being proportional to $\hat{I}_z$, and keeping in mind the time ordering dictated by equations (19) and (20), we find the sequence of values of $\hat{I}_z$, the value of $\hat{I}_z$ in the frame of the rf pulses as indicated in Figure 4, and illustrated by the equations

$$0 < t < \tau : \quad \hat{I}_z = e^{-i0}\hat{I}_ze^{i0} = 1\hat{I}_z1 = 1\hat{I}_z = \hat{I}_z \quad (21a)$$

$$t = \tau : \quad \hat{I}_z = 1\hat{R}_{180y}\hat{I}_z = -\hat{I}_z \quad (21b)$$

$$\tau < t < 2\tau : \quad \hat{I}_z = 1\hat{R}_{180y}1\hat{I}_z = -\hat{I}_z \quad (21c)$$

$$t = 2\tau : \quad \hat{I}_z = 1\hat{R}_{180y}1\hat{R}_{180y}\hat{I}_z = \hat{I}_z \quad (21d)$$

$$2\tau < t < 3\tau : \quad \hat{I}_z = 1\hat{R}_{180y}1\hat{R}_{180y}1\hat{I}_z = \hat{I}_z \quad (21e)$$

The familiar result is that at periodic cycle times $4n\tau$, under the spin echo sequence $(\tau, 180^\circ_y, 2\tau, 180^\circ_y, \tau)n$, chemical shifts, and field inhomogeneities, with spin operators $\hat{I}_{zk}$, vanish (but other interactions, such as homonuclear dipolar coupling, do not). This is to say that at cycle times $4n\tau$, with the internal Hamiltonian being proportional to $\hat{I}_z$, $\hat{\mathcal{H}}_{\text{int}}^{(0)}$ is zero, as explicitly shown by

$$\hat{\mathcal{H}}_{\text{int}}^{(0)}(4n\tau) \approx \frac{1}{4\tau} \int_0^{4\tau} \hat{\mathcal{H}}_{\text{int}} dt = \frac{1}{4\tau} \omega_{\text{CS}} [\hat{I}_z\tau + (-\hat{I}_z)\tau] = 0 \quad (22)$$

Here, ω_{CS} is a product of a constant (γB_{eff}) and the portion of the chemical shift Hamiltonian which is a function of the real space angular variables θ and ϕ considered explicitly earlier when talking about magic angle spinning. We may think of observation at periodic cycle times $t = 4n\tau = nt_c$ as observation in the frame of $\hat{\rho}$.

With the basic ideas outlined above, one may now understand how averaging is accomplished for a more complicated internal interaction than one simply proportional to $\hat{I}_z$. One creates periodic groups of cyclic sequences of

Figure 4 Spin echo sequence (τ , 180°_y , 2τ , 180°_y , τ). Cycle time $t_c = 4\tau$. Also indicated are values of $\hat{\mathcal{H}}_{\text{rf}}(t)$, $\hat{U}_{\text{rf}}(t, 0)$, $\hat{I}_z(t) = \hat{U}_{\text{rf}}^{-1}(t, 0) \hat{I}_z \hat{U}_{\text{rf}}(t, 0)$

Figure 5 Dipolar echo sequence (τ , 90°_x , τ , 90°_y , τ). Cycle time $t_c = 3\tau$. Also indicated are the values of $\hat{\mathcal{H}}_{\text{rf}}(t, 0)$, $\hat{U}_{\text{rf}}(t, 0)$, $\hat{I}_z(t)$, $\hat{I}_{z1}\hat{I}_{z2}(t)$, and $\hat{I}_1\hat{I}_2(t)$

pulses, such that the propagator due to the rf Hamiltonian $\hat{U}_{\text{rf}}(nt_c, 0)$ is unity, and such that the internal Hamiltonian in question $\hat{\mathcal{H}}_{\text{int}}$ becomes time dependent, i.e. becomes $\hat{\mathcal{H}}_{\text{int}}(t)$, and arranges for its time average over a cycle, $(1/t_c) \oint dt \hat{\mathcal{H}}_{\text{int}}(t)$, to be zero. The resulting modulated echo signal in the time domain, when Fourier transformed, yields a spectrum which reflects all other internal Hamiltonians not averaged to zero by the rf pulses.

5 CRAMPS

Applied to the major broadening interaction in proton or in fluorine containing systems, where ^1H or ^{19}F is the only magnetically abundant spin present, the internal interaction

between two protons due to dipolar coupling is given by

$$\hat{\mathcal{H}}_{DII} = \omega_D(\theta)(\hat{\mathbf{I}}_1 \cdot \hat{\mathbf{I}}_2 - 3\hat{I}_{z1}\hat{I}_{z2}) \quad (23)$$

$\omega_D(\theta)$ is the product of a constant and the real space variable θ , the angle between the internuclear vector defining the orientation of the dipole with respect to the external static field. The form need not concern us at this point, except to mention that it must be time-independent. The total dipolar interaction is the sum over all two-body interactions.

Let us denote this two-body interaction by $\hat{\mathcal{H}}_{zz}$, relating to the product of the z components of the two spins in equation (23). Since $\hat{\mathbf{I}}_1 \cdot \hat{\mathbf{I}}_2$ is a scalar product invariant under rotation, pulse sequences will not affect this part of $\hat{\mathcal{H}}_{zz}$. As shown in Figure 5, a 90°_x pulse at time τ rotates the operator $\hat{I}_z$ into the operator $-\hat{I}_y$, via equation (18).

After this 90°_x pulse, therefore, $\hat{\mathcal{H}}_{zz}$ is transformed into $\hat{\mathcal{H}}_{yy}$. A further 90°_y pulse at time 2τ will be seen, using equations (18)–(20), to result in $\hat{\mathcal{H}}_{zz}$ being transformed into $\hat{\mathcal{H}}_{xx}$. Then at a time $t = 3\tau$ the average homonuclear dipolar Hamiltonian [equation (17)] becomes equal to $(\frac{1}{3}\tau)(\hat{\mathcal{H}}_{xx} + \hat{\mathcal{H}}_{yy} + \hat{\mathcal{H}}_{zz})$, which is zero, i.e. the sum $(\hat{I}_1 \cdot \hat{I}_2 - 3\hat{I}_{z1}\hat{I}_{z2}) + (\hat{I}_1 \cdot \hat{I}_2 - 3\hat{I}_{x1}\hat{I}_{x2}) + (\hat{I}_1 \cdot \hat{I}_2 - 3\hat{I}_{y1}\hat{I}_{y2})$ is equal to $3\hat{I}_1 \cdot \hat{I}_2 - 3\hat{I}_1 \cdot \hat{I}_2$. This basic dipolar echo sequence ($\tau, 90^\circ_x, \tau, 90^\circ_y, \tau$) is not cyclic, since the system is not returned to its initial value at time 3τ . However, as explained above, the phase alternated sequence in which the 90°_x pulse is followed by a 90°_y pulse, then by a 90°_{-y} pulse, and then by a 90°_x pulse is cyclic, and incorporates two dipolar echo experiments. This is the WAHUA four-pulse sequence. It was first used with stroboscopic observation, as indicated in Figure 6 (see below) to demonstrate that cyclic periodic sequences of rf pulses could lead to averaging of dipolar interactions with resultant detection of much smaller shielding anisotropies. Improved sequences have been developed to remove the loss of resolution associated with experimental artifacts. Two of the best known are the MREV-8 pulse sequence²¹ and the BR-24 pulse sequence.²²

An example of the increase in length of time decay achieved under the BR-24 pulse sequence is shown in Figure 6. Here, the time decay of the magnetization of protons in high density linear polyethylene under the BR-24 sequence, with observation in the first ten windows of the multiple pulse experiment [Figure 6(a)] and a single pulse excitation [Figure 6(b)] are compared. Since the spectral linewidth is proportional to the inverse of the length of the time decay, we see that the resolution under the homonuclear decoupling has been enormously enhanced, the time decay under the BR-24 sequence lasting more than $20\ \mu\text{s}$, and the decay under a single pulse being over in less than 20 ms. Figure 6(c) shows the Fourier transform of the time decay under the BR-24 sequence, illustrating the shielding anisotropy of protons in high density linear crystalline polyethylene. Combined rotation (MAS) and multiple pulse spectroscopy (CRAMPS) would then collapse the shielding powder pattern to its isotropic value, as shown for adipic acid in Figure 1. Thus combined rotation and multiple pulse spectroscopy, based on the above described ideas, when improved a bit by more complicated pulse sequences to remove loss of resolution due to experimental artifacts, e.g. the MREV-8 and the BR-24 sequences, is the basic CRAMPS technique today.

6 CAVEATS

In the above some implicit assumptions have been made which I will make specific at this point.

1. There exist infinitely fast rf pulses which are ' 90° ' pulses.
2. These rf pulses are in fact much larger than any effects of internal interactions.
3. It is possible to place these pulses sufficiently close together such that the times over which they operate cyclically to bring the system back to its initial state is indeed short compared with dephasing times due to internal interactions.
4. It is possible to observe stroboscopically in the windows between these high-powered pulses.

Figure 6 (a) The first ten points of the stroboscopically observed signal of protons in high density linear polyethylene under the BR-24 sequence. (b) FID under a single pulse excitation. Note that the decay under the single pulse excitation is over in roughly $20\ \mu\text{s}$, whereas the decay under the BR-24 lasts longer than 20 ms. Under MAS, the powder pattern, (c) would collapse to a single line, the isotropic value, obtained in the full CRAMPS experiment, as shown for adipic acid in Figure 1

5. Rotation of the sample does not interfere with the averaging due to spin rotations by the rf pulses.
6. The selective averaging of major broadening interactions (dipolar and shielding anisotropy) does not affect the desired interaction—the isotropic chemical shift.

Each of these assumptions is violated in real experiments to a certain extent:

1. There is no infinitely fast pulse. All rf pulses have a finite width, and have transient phase impurities (the 'phase glitch') associated with them, e.g. a 90°_x pulse will have some transient y phase during the turn-on and turn-off periods. In this multiple pulse experiment with stroboscopic observation of the magnetization, errors in pulse flip angle

and pulse phase rapidly accumulate. For example, a 1° error in flip angle, repeated 1024 times, could result in a 90° pulse becoming a 1114° pulse. To achieve 90° pulses which are sufficiently uniform over the entire sample for this experiment, it is necessary to have an rf coil which is long compared with its diameter. In addition, pulses of a given phase always contain transient phase effects which must be cancelled by use of symmetry adapted pulse sequences. These impurities may be treated theoretically as additional internal interactions which may then be averaged by proper selection of rf pulse sequences.²³

2. Radiofrequency fields of 5 mT are not infinitely large compared with dipolar fields of ca. 0.3 mT, but are indeed good enough, as shown in Figure 1.
3. With dipolar interactions causing line broadening of 20 kHz, it is necessary that the time over which the dipolar echo sequence operates is short compared with 50 ms.
4. Achieving the 3τ cycle time of the dipolar echo experiment, which is short compared with 50 ms, with a 500 W amplifier, and a receiver recovery time short enough to allow stroboscopic observation of the motion of the system in the observation window lasting 2τ s, is a result of careful engineering of solid state spectrometers; this facility is not generally available in spectrometers used for liquid state NMR, and in some commercially sold spectrometers for high-resolution solid state NMR.
5. Physical rotation of the sample can indeed interfere with the selective averaging performed by the multiple pulse sequences.²⁴ This interference can produce an extra peak in CRAMPS spectra which is easily recognizable. There are improved pulse sequences being developed which will help reduce this artifact.²⁵
6. The multiple pulse sequences which severely attenuate dipolar broadening also generally affect the isotropic shielding by scaling shielding differences. In general, the scaling factor depends upon the sequence used, and the length of the rf pulses compared with the 3τ cycle time of the dipolar echo sequence. Under the MREV-8, sequence for example, the scaling factor is roughly $\frac{1}{2}$, so that a chemical shift difference of 10 ppm, measured at a spectrometer frequency of 100 MHz for ^1H , does not translate into 1000 Hz in the observed spectrum, but into 500 Hz. Thus resolution is lost. The scaling factor may be easily determined experimentally.²⁴

1 INTRODUCTION

Diffusion measurements by field gradient methods in this article refer to the measurement of translational diffusion. Rotational diffusion and spin diffusion by means of mutual spin flips are treated elsewhere. Measurements of translational diffusion are important in the determination of sizes and shapes of molecules and molecular aggregates, and NMR in the presence of magnetic field gradients is a uniquely powerful method for making such measurements. The NMR method also provides a means for correlating diffusion coefficients with chemical shifts, characterizing the microgeometry of porous materials, investigating anisotropy of organized phases, and determining degrees of solubilization, to list only a few applications. In this article we present the principles of NMR diffusion measurements and discuss some useful techniques. This represents only a sampling of an extensive field, and we rely on recent review articles to fill in some of the gaps. Also, recent advances that offer new insights and expand the range of applications are emphasized at the expense of some important older contributions. Although some applications appear as examples, a review of applications is not intended. Appropriate textbooks and reviews are cited in the various sections, and Section 12 is devoted to sources for background material and additional reading.

1.1 Fick's Laws

According to Fick's first law of diffusion, the particle flux $\mathbf{J}$ at position $\mathbf{r}$ is proportional to the gradient of the concentration. Thus,

$$\mathbf{J}(\mathbf{r}, t) = -D\nabla c(\mathbf{r}, t) \quad (1)$$

where D is the diffusion coefficient and $c(\mathbf{r}, t)$ is the concentration in number of particles per unit volume. The conservation of mass is assured by the equation of continuity,

$$\frac{\partial c(\mathbf{r}, t)}{\partial t} = -\nabla \cdot \mathbf{J}(\mathbf{r}, t) \quad (2)$$

and this equation can be combined with equation (1) to obtain Fick's second law of diffusion:¹

$$\frac{\partial c(\mathbf{r}, t)}{\partial t} = D\nabla^2 c(\mathbf{r}, t) \quad (3)$$

It is assumed that D has at most a weak dependence on the concentration and that the concentration is low. However, equation (3) is useful over a wide range of concentrations.

In the following it is convenient to introduce the conditional probability $P(\mathbf{r}_0 | \mathbf{r}, t)$ that a particle initially at $\mathbf{r}_0$ will be at $\mathbf{r}$ at time t , and it is reasonable to assume that $P(\mathbf{r}_0 | \mathbf{r}, t)$ also obeys the diffusion equation so that:

$$\frac{\partial P(\mathbf{r}_0 | \mathbf{r}, t)}{\partial t} = D\nabla^2 P(\mathbf{r}_0 | \mathbf{r}, t) \quad (4)$$

The solution of equation (4) by standard means for unrestricted diffusion with the initial condition $P(\mathbf{r}_0 | \mathbf{r}, 0) = \delta(\mathbf{r}_0 - \mathbf{r})$ yields the expected Gaussian dependence on the displacement:

$$P(\mathbf{r}_0 | \mathbf{r}, t) = (4\pi Dt)^{-3/2} \exp[-(\mathbf{r} - \mathbf{r}_0)^2 / 4Dt] \quad (5)$$

The calculation of the average square displacement by means of equation (5) gives the Einstein–Smoluchowski equation:

$$\langle (\mathbf{r} - \mathbf{r}_0)^2 \rangle = 6Dt \quad (6)$$

Thus, molecular displacement resulting from diffusion is simply related to the diffusion coefficient.

1.2 The Stokes–Einstein Equation and Tracer Diffusion

Much of the interest in diffusion arises because of the connection between D and molecular size. For macromolecules, at least, this connection is usually made through the Stokes–Einstein equation:²

$$D = k_B T / f \quad (7)$$

where f is the friction factor. For a spherical particle with hydrodynamic radius R_h immersed in a fluid of viscosity η , Stokes's law gives $f = 6\pi\eta R_h$. Analytical expressions are also available for the friction factors of oblate and prolate ellipsoids and approximate results have been reported for complex structures made of identical subunits.³

The diffusion coefficient of interest here is the tracer diffusion coefficient, sometimes called the self-diffusion or intra-diffusion coefficient.² Nuclear spin states provide perfect labels that have almost no effect on the hydrodynamic properties of molecules. The samples under study are homogeneous and the translational motion of nuclear spins can be detected directly as described below. In a mixture with $N + 1$ components (including the solvent) there are $N + 1$ distinct tracer diffusion coefficients. This must be contrasted with the situation in which there are concentration gradients, and molecular species diffuse into each other in a process called ‘interdiffusion’. The diffusion coefficients measured in such systems are known as the ‘mutual diffusion’ or ‘interdiffusion’ coefficients. In the limit of infinite dilution, tracer and mutual diffusion coefficients are equal, but at higher concentrations they may be quite different. Also, mutual diffusion in mixtures invariably involves coupled flows, and in a volume fixed frame a system with $N + 1$ components has $N(N + 1)/2$ independent Onsager diffusion coefficients.

Dynamic light scattering (DLS), a method that depends on concentration fluctuations, is often used to measure mutual diffusion coefficients.^{4,5} DLS is a standard method, even though the diffusion coefficients obtained are not necessarily equal to the mutual diffusion coefficients that are measured with macroscopic concentration gradients.⁶ At low concentrations NMR and DLS give similar diffusion coefficients for macromolecules in solution, but the dependence on concentration is usually much stronger for tracer diffusion coefficients than for mutual diffusion coefficients. In contrast to equation (7), the mutual diffusion coefficient D_m for a macromolecule can be expressed as

$$D_m = \frac{k_B T}{f} \left(1 + \frac{\partial \ln \gamma'}{\partial \ln c} \right) (1 - \phi') \quad (8)$$

where γ' is the activity coefficient and ϕ' is the volume fraction of solute.^{7,8} Primes have been used here since the same symbols are used elsewhere for different quantities. The last two factors on the right-hand side of equation (8) largely account for the difference between mutual and tracer diffusion coefficients, but in principle the friction factors for mutual and tracer diffusion are not equal.⁹

2 EFFECTS OF TRANSLATIONAL MOTION IN NMR

The ability of NMR to detect translational motion and to image spin density depends on two essential facts: (1) a nucleus at position $\mathbf{r}$ precesses with the frequency

$$\omega(\mathbf{r}) = -\gamma B(\mathbf{r}) \quad (9)$$

where γ is the magnetogyric ratio and $B(\mathbf{r})$ is the magnitude of the local magnetic field (flux density), and (2) the local fields can be manipulated through the use of magnetic field gradients so that the spatial positions of nuclei can be encoded. The spin echo experiment is the basis of NMR diffusion measurements, since this experiment involves the refocusing of magnetization in inhomogeneous magnetic fields, a process that is extremely sensitive to the translational motion of spins.

2.1 Spin Echoes and Magnetization Helices

Consider the experiment illustrated in Figure 1(a) for a sample with a single resonance line. The applied magnetic field is in the z direction and a hard 90°_x rf pulse at $t = 0$ rotates magnetization from all parts of the NMR active volume into the y direction. Here x and y refer to a reference frame rotating about the field direction at the average precession frequency ω_0 for spins in the applied field B_0 . The resultant magnetization in each differential volume element is described by a vector (known as an ‘isochromat’) that precesses in the xy plane at a frequency that depends on the local field as indicated by equation (9). The interpretation is simpler if the inhomogeneity results from a constant field gradient $\mathbf{g}$ applied and controlled externally. Such a gradient is described by:

$$\mathbf{g} = \frac{\partial B_z}{\partial x} \mathbf{i} + \frac{\partial B_z}{\partial y} \mathbf{j} + \frac{\partial B_z}{\partial z} \mathbf{k} \quad (10)$$

where $\mathbf{i}$, $\mathbf{j}$, and $\mathbf{k}$ are unit vectors in the x , y , and z directions, respectively. Thus the magnitude of the total external magnetic field at $\mathbf{r}$ is given by:

$$B = B_0 + \mathbf{g} \cdot \mathbf{r} \quad (11)$$

In the following we assume that only a z gradient of magnitude $g = \mathbf{g} \cdot \mathbf{k}$ is present. In the presence of this gradient, isochromats with different frequencies are associated with different values of z , and it is instructive to represent the magnetization immediately after the 90°_x pulse as a ribbon formed by the isochromats with their tails on the centerline of the sample. Initially, the resultant magnetization in the y direction is equal to M_0 , the magnitude of the equilibrium magnetization prior to the rf pulse. The effect of the gradient is to give the isochromat at coordinate z a phase angle $\phi(z) = \gamma g z t$ with respect to the yz plane at time t . This is represented in Figure 1(b) by the magnetization helices with pitches given by $\Lambda = 2\pi/(\gamma g t)$.¹⁰ The detected signal, that is proportional to the resultant magnetization in the y direction, decays to zero with increasing time as illustrated by the FID in Figure 1(a). In the absence of diffusion the interpretation of the experiment is straightforward. The 180°_y pulse at τ rotates each isochromat about the y axis and thus changes the phase angle of the isochromat at z by the amount $-2\gamma g z \tau$. Precession then continues as before since the local magnetic field is unaffected by the rf pulse. In the period between τ and 2τ the helix unwinds so that the resultant is again directed along the y axis (in the absence of directed flow) and a spin echo signal is created. Thus, the isochromats have been refocused and the only attenuation of the echo results from the intrinsic T_2 of the sample, i.e. the echo amplitude is proportional to $M_0 \exp(-t/T_2)$.

2.2 Bloch Equations including Diffusion

As emphasized in Figure 1(b), the effect of the 90°_x pulse followed by the z gradient is to create a magnetization pattern in the sample. Diffusion smears out this pattern and leads to attenuation of the spin echo. The tightly wound helices are more easily disturbed by diffusion, and analytical equations

Figure 1 Spin echoes with a constant gradient: (a) the Hahn spin echo pulse sequence; (b) magnetization helices formed by isochromats; and (c) the effective gradients in the presence of a 180° rf pulse

can be derived to describe this effect. In the standard mathematical description of this experiment a term describing the rate of translational diffusion of magnetization is added to the Bloch equations to obtain a macroscopic theory of diffusion effects in NMR. Following the notation of Abragam¹¹ this gives,

$$\frac{\partial \mathbf{M}(\mathbf{r}, t)}{\partial t} = \gamma \mathbf{M} \times \mathbf{B}(\mathbf{r}, t) - \frac{M_x \mathbf{i}' + M_y \mathbf{j}'}{T_2} - \frac{(M_z - M_0) \mathbf{k}'}{T_1} + D \nabla^2 \mathbf{M} \quad (12)$$

A more convenient equation for the investigation of transverse magnetization is obtained from equation (12) by defining the complex magnetization $M_+ = M_x + iM_y$, setting $B_x = B_y = 0$, and denoting the magnitude of the average precession frequency in the sample by $\omega_0 = \gamma B_0$. The resulting equation is

$$\frac{\partial M_+}{\partial t} = i\omega_0 M_+ - \frac{M_+}{T_2} - i\gamma (\mathbf{g} \cdot \mathbf{r}) M_+ + D \nabla^2 M_+ \quad (13)$$

The uninteresting parts of the time dependence are then transformed away by means of the substitution

$$M_+ = \psi \exp(i\omega_0 t - t/T_2) \quad (14)$$

to yield the equation¹²

$$\frac{\partial \psi}{\partial t} = -i\gamma g z \psi + D \nabla^2 \psi \quad (15)$$

In the absence of diffusion equation (15) is easily solved for the magnetization in the rotating frame as a function of z and t . If the initial condition is a coherent state created by a 90° rf pulse, the magnetization pattern evolving under the influence of g is just the helix previously described. A gradient pulse with amplitude g and duration δ is said to have an area of $q = \gamma g \delta$, and the helix at the end of the pulse is described by $S(z) = m \exp(-iqz)$, where m is the magnetization density per unit length in the z direction. The integral of the effective gradient areas at the time of the echo must be zero so that the pitch of the helix becomes much larger than the active volume. This can be achieved either by reversing the direction of the gradient to obtain a 'gradient echo' or by applying a 180° pulse to set back the phase to achieve a spin echo. In fact, it is convenient in mathematical derivations to replace 180° rf pulses by the inversion of previous gradient pulses.¹³ The complete sequence of rf and gradient pulses can then be described by an effective $g(t)$. With this approach it has been shown that the solution of equation (15) in the presence of diffusion and a time dependent gradient can be written as

$$\ln \psi = -D \left[\int_0^t q^2(t') dt' \right] \quad (16)$$

where

$$q(t') = \int_0^{t'} \gamma g(t'') dt'' \quad (17)$$

It is important to note that gradient echoes and spin echoes have quite different properties in many experiments. The 180°

rf pulse refocuses phase dispersion resulting from background gradients, chemical shifts, susceptibility effects in heterogeneous samples, etc., while the reversed gradient pulse only refocuses phase dispersion resulting from a previously applied gradient pulse.

2.3 Diffusion Effects on Magnetization Patterns

According to Figure 1, the projection of the helix onto either the xz or the yz plane yields a simple sinusoidal grating function, e.g. $\text{Re}[S(z)] = m \cos(qz)$ for the yz plane. The effect of diffusion (in the direction of the gradient) on such a grating can be obtained immediately through the use of equation (5). First we integrate over the x and y coordinates to obtain

$$P(z_0 | z, t) = (4\pi Dt)^{-1/2} \exp[-(z - z_0)^2 / 4Dt] \quad (18)$$

Then $P(0 | z, t)$ is convoluted with $S(z)$ to obtain an expression for the time dependent gratings. The effect of diffusion is to 'smear out' the spatial gratings, and the time dependent helix is described by $S(z, t) = S(z) * P(0 | z, t)$, where '*' means convolution, and we can write

$$S(z, t) = \frac{m}{(4\pi D\Delta)^{1/2}} \int_{-\infty}^{\infty} \exp(-iqz') \exp[(z - z')^2 / 4Dt] dz' \quad (19)$$

Equation (19) can be evaluated directly or by means of the convolution theorem to obtain

$$S(z, t) = m \exp(-iqz) \exp(-Dq^2 t) \quad (20)$$

This expression includes the amplitude attenuation resulting from diffusion for a helix with a constant q value, i.e. a constant pitch. The attenuation factor can also be recognized as $F(q, t)$, the spatial Fourier transform of $P(0 | \mathbf{r}, t)$:

$$F(q, t) = \int_0^{\infty} P(0 | \mathbf{r}, t) \exp(-iq \cdot \mathbf{r}) d\mathbf{r} \quad (21)$$

The time evolution of $F(q, t)$ is described by the spatial Fourier transform of equation (4). This gives

$$\frac{\partial F(q, t)}{\partial t} = -Dq^2 F(q, t) \quad (22)$$

and we again find that $F(q, t) = F(q, 0) \exp(-Dq^2 t)$. Note that the right-hand side of equation (21) can be interpreted as an average of the phase factor over the distribution of displacements. This viewpoint is explored in Section 5.

2.4 Echo Attenuation in a Constant Gradient

When gradients are present and q is time dependent, $S(z, t)$ in equation (20) describes the evolution of the attenuation factor at a specific time, and the cumulative attenuation is obtained by multiplying together the attenuation factors for

the differential time increments. As expected, this procedure yields the diffusion factor displayed in equation (16).

As an illustration of the use of equation (16), consider the echo attenuation for the simple $90^\circ_x - \tau - 180^\circ_y - \tau$ echo experiment shown in Figure 1. In the regions 0 to τ and τ to 2τ the effective gradient amplitudes are $-g$ and g , respectively, as shown in Figure 1(c), and equation (17) gives

$$q(t) = -\int_0^t \gamma g dt', \quad 0 < t < \tau$$

$$q(t) = -\gamma g \tau + \int_\tau^t \gamma g dt', \quad \tau < t < 2\tau \quad (23)$$

$q(t)$ from equation (23) is then substituted into equation (16) to obtain

$$\ln \psi(2\tau) = -D(\gamma g)^2 \left[\int_0^\tau (t')^2 dt' + \int_\tau^{2\tau} (t' - \tau)^2 dt' \right] \quad (24)$$

Therefore, the attenuation resulting from diffusion at the echo time 2τ is found to be

$$\ln \psi(2\tau) = \frac{1}{12} D \gamma^2 g^2 (2\tau)^3 \quad (25)$$

and the total echo amplitude $S(2\tau)$ is given by

$$S(2\tau) = M_0 \exp(-2\tau/T_2) \exp[-D\gamma^2 g^2 (2\tau)^3 / 12] \quad (26)$$

The well-known τ^3 dependence of the exponent in the diffusion factor is the reason why the simple spin echo experiments are usually not satisfactory for the measurement of T_2 .^{14,15}

3 PULSED FIELD GRADIENT NMR

The introduction of pulsed field gradients (PFGs) in place of steady gradients for diffusion measurements greatly improves the spin echo diffusion experiment and opens a wide range of applications.¹² The basic Stejskal-Tanner experiment, illustrated in Figure 2, has two major advantages over constant gradient methods. First, by confining the gradients to relatively narrow time intervals, this experiment permits gradient areas to be varied without changing the echo time, so that the attenuation resulting from relaxation can be held constant. Second, the echo can be recorded in a homogeneous magnetic field. Spectral information is, therefore, retained and frequency resolved diffusion measurements are possible. These advantages are widely acknowledged, and almost all modern NMR diffusion measurements are made with some form of pulsed gradient experiment. However, a disadvantage of pulsed experiments should be noted. The switched gradient experiments require current pulses that inevitably produce heat, mechanical forces, and eddy currents.

Figure 2 The Stejskal-Tanner pulsed field gradient spin echo diffusion experiment

3.1 The Spin Echo SE Diffusion Experiment

The echo attenuation resulting from diffusion with the sequence shown in Figure 2 can be obtained by direct application of equation (16). The total echo amplitude is given by¹²

$$S(2\tau) = M_0 \exp(-2\tau/T_2) \exp[-Dq^2(\Delta - \delta/3)] \quad (27)$$

where $q = \gamma g \delta$ and the effect of transverse relaxation has been included. The attenuation factor $\psi(2\tau)$ for diffusion alone is easily isolated by taking the ratio of the echo amplitude with applied gradient switched on, $S(2\tau)$, to the amplitude with gradient switched off, $S_0(2\tau)$. Thus $\psi(2\tau) = S(2\tau)/S_0(2\tau)$. However, transverse relaxation diminishes the signal-to-noise ratio and may present a serious problem for slowly tumbling macromolecules and molecular aggregates where T_2 values tend to be short. Transverse relaxation and J modulation effects present special problems for coupled spin systems.^{16,17} T_2 is often much shorter for coupled spins than expected from the rotational correlation times alone, and spin coupling in homonuclear spin systems can prevent complete refocusing of the spin echo. The latter effect arises because hard rf pulses exchange the spin states of nuclei that are coupled to the nuclei under observation. Precession frequencies change, and refocusing depends on the magnitude of the spin coupling constant J . For a coupled pair of spin- $\frac{1}{2}$ nuclei this leads to echo maxima when $\tau = n/J$ and negative echoes when $\tau = n/(2J)$, where n is an integer and J is in hertz.

Equation (27) is appropriate for the analysis of experimental data when the magnetic field B_0 is homogeneous and the gradient pulses are well matched. It may be possible to approximate the effect of an inhomogeneous magnetic field by a constant background gradient g_0 . The effective gradient is then $g + g_0$ and a complete analysis gives the diffusion factor:¹²

$$\begin{aligned} \psi(t) = \exp\{ & -D\gamma^2[g^2\delta^2(\Delta - \delta/3) + 2g_0^2\tau^3/3 \\ & -g \cdot g_0\delta(t_1^2 + t_2^2 + \delta(t_1 + t_2) \\ & + 2\delta^2/3 - 2\tau^2)] \} \end{aligned} \quad (28)$$

Gradient pulse mismatch changes the position and intensity of the echo. Some investigators have resorted to adjusting the

width of the second gradient pulse to reposition the echo, but this is not a practical solution in experiments where the gradient areas are automatically ramped through a series of values and the signal is recorded starting from the center of the echo. A detailed analysis shows that sensitivity to the gradient pulse mismatch is decreased by the application of a constant gradient parallel to the gradient pulses.¹⁸

3.2 The Stimulated Echo Diffusion Experiment

A sequence containing three 90° rf pulses was among the first echo forming sequences studied by Erwin Hahn in his pioneering work on time dependent NMR.¹⁴ He found that five echoes are formed in a steady gradient experiment. As shown in Figure 3(a) they are the primary echo (PE) at $2\tau_1$, the stimulated echo (STE) at $\tau_1 + \tau_2$, and three secondary echoes that are usually not of interest. The effect of diffusion on the STE has been investigated for a steady gradient¹⁹ and for gradient pulses.²⁰ Both versions of the experiment are of current interest (Section 9), but this section focuses on pulsed gradients.

An intuitive understanding of the formation of the stimulated echo can be gained from the graphical representation of the isochromats shown in Figure 3(b). Here the superscripts $(-)$ and $(+)$ indicate 'immediately before' and 'immediately after' the rf pulse at the indicated time. The magnetization ribbon at 0^+ , characterized by $q = 0$, is wound up by the action of the first gradient pulse so that at τ_1^- the pitch of the resulting helix is $\Lambda = 2\pi/q$. In the presence of the gradient pulse and a very weak background gradient, $q \approx \gamma g \delta$. The new feature here is the rf pulse at time τ_1 that rotates each isochromat through 90° about the $-x$ axis so that its y component is stored in the z direction. The resulting pattern of z magnetization is responsible for the STE. At τ_2 the third 90° rf pulse rotates the z magnetization back into the yx plane. If this pulse is directed along the x axis, the isochromats all become collinear with the y axis so that the magnetization lies in the yz plane as represented by the $\cos(qz)$ function shown in Figure 3(b). The refocusing effect necessary to form the STE results from twisting action of the second gradient on this pattern. At the time of the STE the y components of the isochromats are all positive and their resultant reaches a maximum along the y direction, even though they do not all lie in the yz plane. In fact, the projection of the tips of the isochromats onto the xy plane gives a circle tangent to the xz plane. Note that the STE results from a pattern of magnetization density in the z direction, regardless of the source of the pattern. A specially prepared sample with alternating layers having different spin densities can give an STE in an experiment with a single rf pulse.

The magnetization components remaining in the x and y directions after the second rf pulse are responsible for the primary echo and secondary echoes. These components result from the x and z components of the magnetization at τ_1^- . In the pulsed gradient experiment the PE and the secondary echoes do not refocus.

The primary advantage of the STE sequence is that the transverse evolution time for magnetization can be reduced. This is especially important when T_2 is small but, as mentioned above, can also be used to minimize the effects of J modulation. In the absence of a significant background

Figure 3 The pulsed field gradient stimulated echo (STE) diffusion experiment: (a) the pulse sequence and echoes; (b) evolution of the isochromats

gradient, i.e. when $g_0 \approx 0$, the total amplitude of the STE is given by

$$S(T + 2\tau_1) = (M_0/2) \exp(-2\tau_1/T_2 - T/T_1) \times \exp[-Dq^2(\Delta - \delta/3)] \quad (29)$$

Equation (29) also shows the major disadvantage of STE experiments, namely the amplitude of the echo is reduced by a factor of 2 relative to a spin echo (SE) if T_1 and T_2 are equal. The reason for this loss is obvious from Figure 3(b). The second rf pulse only stores the y components, and the second gradient only partially refocuses the magnetization for the STE. This loss may be recovered many times over depending on the ratio of T_2 to T_1 and the amount of attenuation. For example, when $T_2/T_1 = 0.5$ and $T/T_1 = 0.1$ the STE signal is 23% larger than an SE with the same echo time (TE), and when $T/T_1 = 0.5$ the STE is 45 times as large as the SE. It is also advantageous to keep $\tau \ll 1/J$ for spin coupled systems, in order to minimize the modulation of intensities and to make sure that all signals are positive. In general, the advantages of the STE experiment outweigh the loss of signal resulting from the factor of 0.5, and STE is becoming the standard method for diffusion measurements.

3.3 Special Sequences for Heterogeneous Samples

In some cases background gradients cannot be ignored. When the background gradients are uniform, corrections

can be applied to the attenuation factor as shown in equation (28) for the spin echo experiment. However, in heterogeneous samples where the background gradients g_0 have random magnitudes and directions and may be comparable in magnitude to the applied gradients, simple corrections are not possible. Fortunately, pulse sequences can be designed to minimize the corrupting effects of the background gradients. A useful principle is that a 180° rf pulse refocuses isochromats dispersed by a time independent gradient, but that refocusing of the effects of an applied gradient g_A can be avoided either by changing the polarity of the gradient or by applying the gradient pulse on one side of the 180° rf pulse. A number of sequences have been proposed to minimize the effect of the cross term $g_0 \cdot g_A$. Here two schemes are used as illustrations, one for SE and one for STE experiments.

The Karlicek-Lowe (KL) alternating PFG sequence is shown in Figure 4.²¹ Background gradients are effectively reversed by the second 180° rf pulse, but the effective applied gradient g_A is unchanged. The third 180° pulse begins the refocusing period, since the applied gradient is not reversed this time. Note that the intervals δ_1 and δ_2 have been introduced in the pulse sequence so that the rf pulses and the gradient pulses will not overlap. The general version of this sequence has n 180° pulses and the echo occurs at $2n\tau$. The cross term $g_0 \cdot g_A$ is avoided by requiring that the number of positive g_A intervals equal the number of negative g_A intervals, thus restricting n to the values (5, 9, ..., $4m +$

Figure 4 The Karlicek-Lowe alternating pulsed field gradient experiment for minimizing the effects of background gradients²¹

1; $m = 1, 2, 3, \dots$). The effect of the complete sequence on the echo amplitude can be calculated by means of equation (16), with the simplifying assumption that 180° pulses can be replaced with gradient reversals. The solution for the general sequence is:

$$\ln[\psi(2n\tau)] = \frac{-2\gamma^2 D}{3} \left\{ n g_0^2 \tau^3 + (n-1)^3 g_A^2 \left[\tau - \frac{(\delta_1 + \delta_2)}{2} \right]^2 \left[\tau + \frac{(\delta_1 + \delta_2)}{(n-1)^2} \right] \right\} \quad (30)$$

This sequence has been demonstrated with heterogeneous samples having g_0 values of nearly 3 kG cm^{-1} . It has also been used in imaging applications to determine the spatial distribution of diffusion coefficients.²¹

The KL sequence is effective, but is at a disadvantage for samples having T_2 much smaller than T_1 . In order to deal with short transverse relaxation times Cotts et al.²² have proposed a number of sequences based on the STE diffusion experiment. The standard STE pulsed gradient diffusion sequence in the presence of a background gradient g_0 is shown in Figure 5(a) and the attenuation factor obtained by Tanner is given by^{20,22}

$$\begin{aligned} \ln[\psi(\Delta + 2\tau)] = & -\gamma^2 D \left\{ \delta^2 \left(\Delta + \tau - \frac{\delta}{3} \right) g_A^2 \right. \\ & + \delta \left[2\tau\Delta + 2\tau^2 - \frac{2\delta^2}{3} \right. \\ & \left. \left. - \delta(\delta_1 + \delta_2) - (\delta_1^2 + \delta_2^2) \right] \right. \\ & \left. \times g_A \cdot g_0 + \tau^2 \left(\Delta + \frac{2\tau}{3} \right) g_0^2 \right\} \quad (31) \end{aligned}$$

A sequence that eliminates the cross term $g_0 \cdot g_A$ when $\delta_1 = \delta_2$ and reduces the effect of g_0^2 is shown in Figure 5(b). The attenuation factor calculated for this 13 interval sequence is

$$\begin{aligned} \ln[\psi(\Delta + 4\tau)] = & -\gamma^2 D \left[\delta^2 \left(4\Delta + 6\tau - \frac{2\delta}{3} \right) g_A^2 \right. \\ & \left. + 2\tau\delta(\delta_1 - \delta_2) g_A \cdot g_0 + \frac{4\tau^3 g_0^2}{3} \right] \quad (32) \end{aligned}$$

A number of more effective but also more complicated sequences have been designed. For example, a 17 interval sequence that is the STE version of the KL sequence with storage at 6τ and recovery of transverse magnetization at $\Delta + 6\tau$ has the advantages of the 13 interval sequence but gives a

Figure 5 (a) The standard stimulated echo (STE) sequences with a background gradient. (b) A 13 interval STE sequence for minimizing the effects of background gradients²²

larger coefficient for g_A^2 . An extension to n pairs of gradient pulses ($n \leq 12$) has been found to be even more effective in eliminating the effects of g_0 .²³

3.4 Modulated Gradients

Modulated gradients, in particular gradients with sinusoidal time dependence, have been suggested as alternatives to pulsed gradients.^{12,24} Modulated gradients may be easier to implement than pulsed gradients and may cause less trouble with eddy currents in metal magnet structures. These advantages have not yet attracted many users. However, modulated gradients should be of interest for another reason: they introduce flexibility into NMR studies of motion and may permit frequency-dependent diffusion coefficients to be studied that are inaccessible with conventional PFG-NMR experiments.^{25,26}

In transport theory the frequency dependent self-diffusion tensor is defined as the spectrum of the velocity correlation function:

$$D_{\alpha,\beta}(\omega) = \frac{1}{2} \int_{-\infty}^{\infty} \overline{v_{\alpha}(0)v_{\beta}(t)} \exp(i\omega t) dt \quad (33)$$

where α and β represent the Cartesian coordinates x, y, z . In order to investigate the frequency dependence of $D_{\alpha\beta}(\omega)$, Stepisnik²⁶ has developed a general theory for the echo attenuation exponent $\alpha(t)$, defined by $\psi \propto \exp[-\alpha(t)]$, in the presence of a modulated gradient. Under certain conditions $\alpha(t)$ can be expressed as

$$\alpha(t) = \frac{1}{2\pi} \gamma^2 \int_{-\infty}^{\infty} D_{zz}(\omega) S(\omega, t) d\omega \quad (34)$$

where

$$S(\omega, t) = \frac{|\mathbf{g}(\omega, t)|^2}{\omega^2}, \quad \mathbf{g}(\omega, t) = \int_0^t \mathbf{g}_{\text{eff}}(t') \exp(-i\omega t') dt' \quad (35)$$

Here $\mathbf{g}_{\text{eff}}(t)$ includes inversions to account for 180° pulses, as discussed in Section 2.2. Equation (34) shows that echo

Figure 6 Sinusoidal modulation: the gradient $g_{\text{eff}}(t)$ and its spectrum $S(\omega, t)$ ²⁵

attenuation depends on the spectral density of molecular motion and the spectrum of the gradient.

This ‘gradient spectrum’ formulation is consistent with the Stejskal–Tanner result for the conventional gradient echo experiment that depends on $D(0)$. The power of Stepisnik’s method is revealed with modulated gradients that offer the possibility of probing the frequency dependence of $D(\omega)$. For example, Figure 6 shows a sinusoidal gradient with amplitude g and its spectrum, and the application of equation (34) gives:

$$\alpha(t) = \frac{\gamma^2 g^2}{\omega_m^2} t [D_{zz}(0) + \frac{1}{2} D_{zz}(\omega_m)] \quad (36)$$

Therefore, $D(\omega)$ can be investigated by measuring $\alpha(t)$ for different modulation frequencies. It has been pointed out that this technique permits rapid motions to be investigated without reducing the evolution period.

3.5 Radiofrequency Field Gradients

The difficulties encountered in producing large pulsed gradient fields and in controlling the induced eddy currents are well known. A method that avoids these problems, albeit at some cost, is the use of rf field gradients in place of B_z gradients. This is essentially an extension of the rotary echo method to diffusion measurements.²⁷ A single turn rf coil around the x axis in the laboratory frame provides a B_1 field gradient, g_1 perpendicular to the B_0 field. The result is phase encoding of x positions, so that a helix of magnetization lies along the x axis. One implementation of this method (Figure 7) uses two rf coils to produce homogeneous and inhomogeneous rf fields.²⁸ An inhomogeneous pulse of length δ imparts the phase angle $\gamma g_1 x \delta$ in the yz plane at x . A homogeneous (hard) 180°_y pulse reverses the sign of the phase, and the second inhomogeneous pulse unwinds the helix to refocus magnetization along the z axis. Finally, a hard 90°_x pulse rotates the magnetization into the y direction in the rotating frame so that the signal can be detected.

The effect of diffusion is to smear out the helix as in the conventional PFG-SE experiment, and the same arguments lead to the exponential attenuation factor in equation (27). However, the effect of spin relaxation is different with rf gradients. If $T_2 \gg \Delta$, the magnetization is completely recovered by the second gradient pulse in the absence of

Figure 7 Sequence for rf gradient diffusion measurements with two coils: rf gradients g_1 and hard 90° and 180° pulses are shown²⁸

diffusion. However, with $T_2 \ll \Delta$ the isochromats are parallel to the z axis at the beginning of the second inhomogeneous pulse and refocusing only recovers half of the initial magnetization as recovered in STE experiments. Net transverse magnetization can also be removed by means of an inhomogeneous B_0 field during Δ to ensure the rotary equivalent of the STE experiment. The signal at $\Delta + \delta$ is known as a ‘stimulated rotary echo’ (SRE).²⁹ There is also an echo at 2Δ that is T_2 -weighted but may be useful for diffusion measurements. It turns out that the SRE experiment can be implemented with a single rf coil and without the hard 180_x and 90_x rf pulses. As in the STE experiment the 180_x pulse is not needed, and in place of the 90_x rf pulse the second inhomogeneous pulse can be lengthened by the amount τ that corresponds to a 90° rotation for isochromats at the center of the sample.

The rf gradient experiments are successful and provide convenient gradient switching without harmful eddy currents. Unfortunately, the gradient amplitudes are limited. The largest g_1 reported to date is 15.2 G cm^{-1} , and the measurement of small diffusion coefficients requires rf pulse lengths greater than 10 ms. Still a diffusion coefficient of $3.3 \times 10^{-8} \text{ cm}^2 \text{ s}^{-1}$ has been measured to within 5%, and the method is promising.²⁹

3.6 Multiple Quantum Diffusion Measurements

Multiquantum (MQ) NMR experiments have the following advantages for the study of molecular diffusion: (a) precession frequencies increase linearly with the order $n = \Delta m$ of the coherence; (b) MQ spectra are simplified with respect to the single quantum spectrum; and (c) for N coupled protons the N -quantum transition is free of dipolar couplings. The possible limitations are that the spectrum must show splittings from scalar, dipolar, or quadrupolar coupling; and that, except for double quantum excitations, there is a loss of sensitivity because of the inefficient transfer of magnetization.

The first two demonstrations of MQ diffusion measurements involved solutes in liquid crystal solvents where dipolar splittings are evident.^{30,31} For example, benzene in a nematic phase diffusion permits measurements to be made with $n = 1$ to 6 by means of the pulse sequence shown in Figure 8.³¹ In this sequence MQ orders are present during the diffusion period Δ and at the MQ echo. A short gradient pulse after the echo, but during the MQ evolution, and a set of n gradient pulses after recall of single quantum coherence provide the n -quantum filter. The effective gradient is increased by a factor

Figure 8 The multi-quantum (MQ) diffusion experiment: (a) sequence for multi-quantum excitation and n -quantum filtering; (b) echo intensities for coherences with $n = 1$ to 6 for benzene in a nematic solvent³¹

of n for the n -quantum coherence and the echo attenuation factor becomes:

$$\psi(t_1) = \exp[-n^2 \gamma^2 g^2 \delta^2 D(\Delta - \delta/3)] \quad (37)$$

This effect is elegantly illustrated by the plot of echo amplitudes for benzene shown in Figure 8(b). While this experiment may be most valuable for slow moving molecules in anisotropic environments, it can also provide enhanced gradients and MQ filtering in isotropic phases when scalar coupling is present.^{32,33}

The use of zero quantum coherences in diffusion studies has been discussed in connection with the use of static gradients and the avoidance of eddy current effects.³⁴ However, high resolution is still obtained by switching off the gradient before data acquisition.

4 THE FT-PFG-NMR METHOD AND DIFFUSION ORDERED TWO-DIMENSIONAL NMR SPECTROSCOPY

The measurement of spin relaxation in complex systems by FT methods was suggested and demonstrated by Vold et al.³⁵ Their example was an inversion recovery experiment for the measurement of T_1 , but frequency resolved measurements of transverse relaxation and diffusion rates were also discussed. The simultaneous measurement of diffusion coefficients for all components in a mixture was demonstrated by James and McDonald³⁶ with a spin echo experiment similar to that illustrated in Figure 2 except that the gradient was on almost the full time between the rf pulses. The second half of the spin echo at 2τ was Fourier transformed to obtain the complete spectrum of a mixture of dimethyl sulfoxide (DMSO) and water, and the experiment was repeated for 10 values of

τ . The ratios of the peak intensities with and without the gradient pulses then gave the diffusion factor $\psi(2\tau)$ for each line. This type of experiment has been implemented on FT NMR spectrometers and applied to a variety of chemical systems.^{37–39} The work of Stilbs and coworkers in particular stimulated much interest in diffusion measurements. An early example of the FT-PFG-NMR experiment for a mixture containing chloroform, benzene, dichloroethane, 1,4-dioxane, acetone, cyclopentane, cyclohexane, and tetramethylsilane is shown in Figure 9.⁴⁰ The gradient pulse amplitude was approximately 1.2 G cm^{-1} and the different values of q were obtained by varying the duration δ as shown on the right-hand side of the figure.

FT-PFG-NMR experiments demonstrate that information about diffusion and flow can be encoded into high-resolution data sets. This is very important because it addresses the shortcoming of NMR as an analytical tool. High-resolution NMR is highly selective because it reports on details of the local environments of nuclei, i.e. short range interactions. However, NMR is not sensitive to long range interactions of nuclei ($>1 \text{ nm}$) and is only indirectly affected by the overall sizes and charges of macromolecules and molecular aggregates. Therefore, NMR is not particularly good for the analysis of complex mixtures. However, hydrodynamic properties do depend on size and charge, and FT-PFG-NMR opens the door to the utilization of this information in NMR analysis.

Diffusion ordered two-dimensional NMR (DOSY) is primarily concerned with the analysis and display of data obtained in FT-PFG-NMR experiments.⁴¹ Plots of signal intensities versus gradient pulse lengths, or areas, are somewhat analogous to FIDs. The data sets can be analyzed to determine one or possibly more diffusion coefficients, but the results are not obvious by inspection of the decay curves. Just as FIDs are Fourier transformed to obtain ‘user-friendly’ frequency spectra, diffusion dependent decays can be transformed to obtain ‘diffusion spectra’. DOSY experiments are designed to acquire automatically high-resolution NMR data sets for an exponentially spaced set of q values. The frequency spectra are obtained by Fourier transformations and the data sets at each chemical shift are inverted by approximate inverse Laplace transforms (ILTs) with respect to q^2 to generate two-dimensional diffusion spectra.

Signal stability is crucial in DOSY, and the following features have been incorporated: (i) the gradient pulses are matched within 10 ppm so that the echo positions do not vary as q is changed;⁴² (ii) currents induced by the gradient pulses are minimized through the use of actively shielded gradient coils;^{43,44} and (iii) signal distortions resulting from residual eddy currents are avoided through storage of the echo signal while the eddy currents decay. The pulse sequence chosen for this experiment is the ‘longitudinal eddy delay’ (LED) sequence shown in Figure 10.⁴⁵ This is a modified STE sequence with a fourth rf pulse to store the STE and a fifth rf pulse to recall the magnetization after the eddy current settling period. The gradient prepulses establish a steady state response so that the fourth and fifth gradient pulses will have equivalent effects.⁴⁶ Note that $\Delta = T + \tau$ and, in general, $\tau \ll T$, so that the evolution period for transverse magnetization between the first rf pulse and the STE is negligible. Also, phase cycling of the five rf pulses and a homospoil gradient pulse during T_e are used to eliminate the secondary echoes. With this

Figure 9 FT-PFG-NMR stack plot for a multicomponent mixture. The gradient pulse amplitude is constant, and the pulse duration δ increases from back to front⁴⁰

Figure 10 The LED pulse sequence. The phase cycling and homospoil pulse during T_e are not shown

system diffusion coefficients down to $10^{-10} \text{ cm}^2 \text{ s}^{-1}$ have been measured for gel stabilized samples. The lower limit for low viscosity samples is usually determined by convection currents resulting from temperature gradients.⁴⁷

In DOSY, FIDs are acquired for 20–50 exponentially spaced q values and are Fourier transformed to obtain frequency spectra. The result is a two-dimensional data set of the form

$$f(q, \nu) = \sum_{j=1}^{N_\lambda} A_j(\nu) \exp[-D_j(\Delta - \delta/3)q^2] \quad (38)$$

where $A_j(\nu)$ is the one-dimensional NMR spectrum of the j th diffusing species when $q = 0$ (taking into account transverse and longitudinal relaxation), D_j is the associated tracer diffusion coefficient, and N_λ is the number of components required for the fit. The aim is to analyze the data set for each frequency ν so that a set of amplitudes A_j and diffusion coefficients D_j is obtained. This set is then used to generate a diffusion spectrum with peak positions and amplitudes that correspond to the D_j and A_j values, respectively.

Unfortunately, the fitting of data (with noise) with an equation of the form of equation (38) is an ill-conditioned problem, and infinitely many sets of solutions may fit the data very well (see Section 10). Since it is not sufficient to fit the data, additional information must be introduced to aid in selecting the most likely solution for a real mixture. The first decision is whether the sample contains components with

well defined (discrete) diffusion coefficients or if continuous distributions, i.e. polydispersity, must be considered. In the discrete case, data inversion programs such as DISCRETE^{48,49} and SPLMOD^{50,51} are appropriate for automated analysis since they do not require initial estimates of the parameters, but they must be supplemented with prior knowledge about the nature of the acceptable solutions. For example, signal amplitudes in LED experiments (with $\tau \ll \Delta$) and decay constants (diffusion coefficients) must be nonnegative. Also, the range of physically acceptable diffusion coefficients, the diffusion coefficients accessible to the PFG-NMR experiment, and the resolving power of the SPLMOD analysis are known. This knowledge combined with data analysis experience led to the following conservative set of acceptability criteria:

1. Diffusion coefficients must be feasible and experimentally accessible.
2. Standard errors in diffusion coefficients reported by SPLMOD must be less than 30%.
3. Diffusion coefficients of components at the same chemical shift must differ by a factor of more than 2.

These rules are included in a computer algorithm so that frequently occurring artifacts can be rejected.

When a solution has been found that meets the criteria at each frequency in the NMR spectrum, the DOSY display is generated with normalized Gaussians having center positions and intensities equal to the derived diffusion coefficients and amplitudes, respectively. Thus, the DOSY display has the form

$$F(D, \nu) = \sum_{j=1}^{N_\lambda} A_j(\nu) G_j(D) \quad (39)$$

where

$$G_j = \frac{1}{\sqrt{2\pi}\sigma_j} \exp\left[-\frac{(D - D_j)^2}{2\sigma_j^2}\right] \quad (40)$$

Here σ_j is derived from the error reported by the analysis program with an allowance for systematic errors. An example

Figure 11 DOSY display processed with SPLMOD for a mixture containing toluene, benzyl alcohol, tetraethylene glycol (TEG), and SDS micelles in D_2O .⁵² The degrees of solubilization p_j are given in parentheses

of the application of DOSY to a discrete mixture is shown in Figure 11.⁵² The various solutes are solubilized by the surfactant sodium dodecyl sulfate (SDS). The solutes exchange between SDS micelles and the bulk solution so rapidly that the PFG-NMR experiment reports only the time averaged diffusion coefficient for each species. Therefore, for the j th solute the observed diffusion coefficient D_j is given by^{53,54}

$$D_j = p_j D_j^{\text{mic}} + (1 - p_j) D_j^{\text{free}} \quad (41)$$

where p_j is the degree of solubilization, and D_j^{mic} and D_j^{free} are the tracer diffusion coefficients for solubilized and free molecules, respectively. The diffusion coefficients in this example are so similar that resolution in the NMR dimension is essential for a complete analysis. High-resolution spectra were obtained in this experiment by means of a stop-and-go spinner system that permitted the sample to be stationary during the diffusion time Δ but to spin during data acquisition.⁵⁵

Continuous distributions are encountered with many systems of interest. Examples include micelles, microemulsion droplets, vesicles, and polymers. Equation (38) can be rewritten to emphasize the continuous distribution $g(\lambda)$ of diffusion coefficients contributing to the data set at a particular frequency ν . Thus

$$G(s) = \int_0^\infty g(\lambda) \exp(-\lambda s) d\lambda \quad (42)$$

where $\lambda = D$ and $s = q^2(\Delta - \delta/3)$. The factoring of the exponent in equation (38) is a matter of convenience, and in cases where $(\Delta - \delta/3)$ is constant one might choose $s = q^2$. The inversion of a data set $G(s)$ containing noise to obtain the diffusion spectrum $g(\lambda)$ is a long-standing problem in data analysis, and its ill-posed nature has been emphasized repeatedly. A large body of literature has been devoted to this problem (see Section 10). The ill-conditioned inverse Laplace transform ILT has been approached by a variety of methods including regularized least-squares (CONTIN) and maximum entropy (MEM). Thus far only CONTIN has been applied to DOSY analyses.^{41,56} In this program the linear least-squares method is augmented with prior knowledge about the nature of the solutions and the principle of parsimony. We know that the decay constants (diffusion coefficients) are nonnegative

Figure 12 DOSY display preprocessed with CONTIN for a mixture containing CTAB, PVME, and NaSal (see text)⁵⁷

and that the decay kernels are exponential. Also, as noted above, the LED experiment ensures that the signal amplitudes are positive. Parsimony implies that the simplest (smoothest) solution consistent with a priori information and the data is selected. This amounts to discriminating against solutions with high-frequency components (wiggles) by introducing a term to penalize such solutions. The weight given to the penalty is the regularization parameter α that is determined on the basis of the Fisher F -test or by input from the user. Therefore, CONTIN provides an automatic analysis that has some capability to handle multimodal distributions. The primary shortcoming is that enforced smoothness reduces the ability to resolve peaks in the diffusion spectrum and leads to overestimation of the widths of narrow peaks.

The generation of DOSY displays with CONTIN is straightforward. The $G(s)$ versus s data sets are analyzed at every frequency point where the signal-to-noise ratio exceeds a predetermined threshold value to obtain new data sets of intensities versus values of D . Stack plots or contour plots are then constructed without any additional data manipulation. An example of a CONTIN analysis is provided by the DOSY display in Figure 12 for a sample containing 25.0 mM hexadecyltrimethylammonium bromide (CTAB), 15.0 mM sodium salicylate (NaSal), and 7.40 g L⁻¹ poly(vinyl methyl ether) (PVME) at 30 °C.⁵⁷ The projections on the left-hand side show diffusion distributions for PVME, CTAB, and NaSal. The addition of PVME to the viscoelastic CTAB/NaSal sample resulted in a marked reduction in the viscosity. It is thought that the polymer reduces the length of threadlike CTAB micelles by wrapping around the micelles. Note that the polydispersity of the polymer is consistent with the width of the distribution, but that the associated CTAB shows a much narrower distribution. The width for CTAB results primarily from regularization in the analysis, since CTAB molecules exchange rapidly between aggregates associated with different PVME molecules and exchange narrowing is expected. Figure 12 also shows the smoothing effect of CONTIN on the distribution for NaSal which is monodisperse and should have a vanishingly small width. When preliminary analysis indicates that a relatively narrow unimodal distribution of diffusion coefficients is present at a particular chemical shift, the direct cumulants analysis method may be preferable to CONTIN (see Section 10).

5 THE AVERAGE PROPAGATOR AND THE SCATTERING ANALOGY

In the short gradient pulse limit ($\delta \ll \Delta$) the equations given in Section 2 for the echo amplitude can be recast in a useful and instructive form. Consider the SE experiment illustrated in Figure 2 with gradient pulses of amplitude g in the z direction. The first gradient pulse instantaneously encodes the phase shift $-\gamma\delta g z_0$ for spins at position z_0 . During the interval Δ the spins diffuse a distance Z parallel to the gradient to the position $z_0 + Z$, and finally the second gradient pulse, inverted relative to the first one or effectively inverted by a 180° rf pulse, gives the additional phase shift $\gamma\delta g(z_0 + Z)$. Thus, the net phase shift is $\gamma\delta g Z$ for spins starting at time zero. Of course, the echo arises from all of the excited spins and depends on both the initial spatial distribution of spins $\rho(z_0)$ and the conditional probability $P(z_0 | z_0 + Z, \Delta)$ that a spin at z_0 at time zero will be at $z_0 + Z$ at time Δ . The sum over all NMR active spins leads to the expression⁵⁸

$$\psi = \int \rho(z_0) P(z_0 | z_0 + Z, \Delta) \exp(iqZ) d(z_0 + Z) dz_0 \quad (43)$$

where again $q = \gamma\delta g$ and spin relaxation has been neglected.

We now define the ‘average propagator’

$$\bar{P}(Z, \Delta) = \int \rho(z_0) P(z_0 | z_0 + Z, \Delta) dz_0 \quad (44)$$

so that the echo amplitude can be written as

$$\psi(q) = \int \bar{P}(Z, \Delta) \exp(iqZ) dZ \quad (45)$$

This reveals the Fourier transform relationship between $\psi(q)$ and $\bar{P}(Z, \Delta)$ and indicates that $\bar{P}(Z, \Delta)$ can be obtained as the Fourier transform of the echo amplitude.^{59, 60} Note that for free diffusion in a homogeneous sample, the average propagator is simply the Gaussian function shown in equation (18) with Δ in place of t . Substitution of equation (18) into equation (45) gives

$$\psi(q) = 2(4\pi D \Delta)^{-1/2} \int_0^\infty \exp(-Z^2/4D\Delta) \cos(qZ) dZ \quad (46)$$

and evaluation of equation (46) shows that the echo amplitude is just $\psi(q) = \exp(-Dq^2\Delta)$, as previously derived. In general, the shape of the propagator $\bar{P}(Z, \Delta)$ is determined by average molecular displacements in the sample under study. An example is provided by the diffusion of ethane in NaCaA zeolites;⁵⁹ for further information see *Diffusion in Porous Media*.

It has been pointed out that the Fourier transformation of $\psi(q)$ provides an image of the propagator analogous to the image of spatial positions provided by magnetic resonance imaging (MRI). The q space introduced here is conjugate to the dynamic displacement space $\mathbf{R}$ or Z .

Equation (46) suggests an analogy with scattering experiments, in particular dynamic light scattering (DLS), neutron scattering, and holographic relaxation spectroscopy (HRS). In

Figure 13 Scattering of a plane wave from a particle at $\mathbf{r}_j$ and the reference point (+)

the idealized scattering experiment an incident plane wave having the wave vector $\mathbf{k}_i$ of magnitude $2\pi/\lambda$ is scattered through an angle θ_s by suspended particles. The scattered wave is described by the wave vector $\mathbf{k}_s$ that has a different direction but the same magnitude as the wave vector of the incident wave. In DLS we are concerned with the relative phase ϕ_j of the electric field E_s of the light scattered by the j th scatterer at the detector. This phase angle depends on the path lengths and, as illustrated in Figure 13,

$$\phi_j = \mathbf{k}_i \cdot \mathbf{r}_j - \mathbf{k}_s \cdot \mathbf{r}_j = \mathbf{q} \cdot \mathbf{r}_j \quad (47)$$

where elementary trigonometry shows that $|q| = (4\pi/\lambda) \sin(\theta_s/2)$. The quantity derived from DLS data is the reduced first-order correlation function $g^{(1)}(\tau)$ defined by

$$g^{(1)}(\tau) = \frac{\langle E_s^*(0) E_s(\tau) \rangle}{\langle |E_s(0)|^2 \rangle} \quad (48)$$

If the motions of the scatterers are independent and certain other conditions are satisfied, only ‘self-correlation’ terms are important and equations (47) and (48) can be combined to obtain:^{5, 61}

$$|g^{(1)}(\tau)| = \langle \exp\{i\mathbf{q} \cdot [\mathbf{r}_j(\tau) - \mathbf{r}_j(0)]\} \rangle \quad (49)$$

where $\langle \rangle$ represents an average over all scattering particles. This, of course, is equivalent to equation (43) for a uniform distribution of scatterers with τ in place of Δ . The discussion of DLS also applies to neutron inelastic scattering, except that the self-correlation function is available directly without assumptions about independent motions of scatterers from the neutron scattering function for the incoherent fraction.

In DLS the scattering angle determines the magnitude of q and $\sin(\theta_s/2)$ plays a role similar to that of the gradient area in NMR. Similarly, the diffraction spot in DLS is analogous to the spin echo in NMR. This analogy can be pursued to show why DLS and PFG-NMR measure different types of diffusion coefficient. The key to the difference is the condition necessary for there to be a signal. In the case of light scattering a perfectly uniform distribution of scatterers, as for example in a perfect crystal, cannot produce a diffraction spot since light

scattered by the different scattering centers will interfere and cancel at the detector. The way to get around this problem is to arrange the scatterers so that they behave as a diffraction grating and produce intensity at the desired scattering angle. That is what actually happens in a solution or suspension of particles. Instantaneous concentration fluctuations have Fourier components that scatter light in various directions. This is why a grainy pattern of twinkling speckles is observed when light from a laser beam is scattered by a solution onto a flat surface. The important point is that the concentration of scatterers must vary with position, and time-dependent concentration changes result from mutual diffusion in the presence of concentration gradients.

In NMR it is well known that a single 90° rf pulse cannot produce a spin echo for a uniform sample. After the FID there is complete interference and the isochromats do not refocus. A close analogy with the optical case is found in the STE experiment. Here the magnetization pattern, created prior to the third 90° pulse, plays the role of a 'diffraction grating'. The 90° rf pulse rotates the isochromats into the xy plane where they evolve under the influence of a gradient until an echo is formed. The vector addition problem is identical to that found for the electric field in small angle light scattering. However, STE formation does not require spatial variations in the concentrations of particles but rather in the spin polarization (or phases) of the nuclei. Therefore, PFG-NMR detects tracer diffusion. It is, of course, possible to measure mutual diffusion with NMR by creating a periodic concentration pattern, as discussed in Section 3.2.

HRS provides an even more obvious analogy with the STE experiment.^{10,62,63} In HRS two monochromatic laser beams are crossed at a small angle in a sample to form an interference pattern that in turn produces a volume hologram of photoproducts. In the low intensity limit the concentration of the j th photoproduct can be expressed as:

$$c_j(z, t) = \langle c_j \rangle + c_{1j} \cos(qz) \quad (50)$$

where $\langle \rangle$ represents an average over space and c_{1j} is the amplitude of the grating. The time evolution of the grating is monitored by a laser probe beam incident on the sample at the Bragg angle. In a heterodyne experiment where the diffracted light is mixed with a reference beam, the electric field of the diffracted light is determined and the amplitude of the grating can be mapped as a function of time. If photoexcitation changes optical properties and not hydrodynamic properties, this experiment permits tracer diffusion rates to be measured.

Analogies also appear in the spatial imaging of gratings. In the optical grating experiment a Fourier transformation of the electric field of the diffracted light with respect to the scattering angle yields an image of the diffracting grating. In the simplest case the diffraction spot is represented by a delta function at the angle θ_s and the grating is a cosine function. In the STE experiment an image of the magnetization grating can be obtained by reading out the stimulated echo in the presence of a constant gradient and Fourier transforming the signal with respect to time measured from the third 90° rf pulse. Images of transient magnetization gratings (TMGs) are useful for monitoring the spatial dependence of diffusion and flow.¹⁰ In the medical literature this method is known as 'spatial manipulation of magnetization' (SPAMM).⁶⁴

6 RESTRICTED DIFFUSION AND DIFFUSIVE DIFFRACTION

A significant fraction of NMR diffusion studies have been devoted to the restricted diffusion of fluids since Woessner's studies of porous materials with CW gradients.⁶⁵ PFG-NMR studies of restricted diffusion date from the pioneering work of Tanner and Stejskal.⁶⁶ Their procedure was to solve the diffusion equation with appropriate boundary conditions for $P(r | r', t)$ and to determine the echo amplitude by means of equation (43). Echo amplitudes have been derived for systems where diffusion is restricted by reflecting surfaces in the form of parallel planes, cubic cavities, cylinders, and spheres for steady gradients⁶⁷ and pulsed gradients.^{66,68} There is much current interest in the study of porous materials by means of PFG-NMR.

The spherical cavity provides an important model for restricted motion in pores and in biological cells and vesicles. This case was treated by Neuman⁶⁷ for a steady gradient assuming a Gaussian distribution of phases at the time of the echo, and the calculation was later extended by Murday and Cotts⁶⁸ to the pulsed gradient SE experiment. The pulsed gradient solution is shown in equation (51) for a sphere of radius R :

$$\ln[\psi(q)] = -2\gamma^2 g^2 \sum_{m=1}^{\infty} \frac{1}{\alpha_m^4 D (\alpha_m^2 R^2 - 2)} \times \left(2\delta - \frac{2 + x_m^{\tau-\delta} - 2x_m^\delta - 2x_m^\tau + x_m^{\tau+\delta}}{\alpha_m^2 D} \right) \quad (51)$$

Here $x_m = \exp [-(\alpha_m^2 D)]$ and α_m is the m th root of the equation

$$(\alpha_m^2 R^2 - 2) \sin(\alpha_m R) + 2\alpha_m R \cos(\alpha_m R) = 0 \quad (52)$$

The parameters τ , δ , and g are defined in Figure 2, except that here $\tau = \Delta$. In the short time limit ($\Delta \ll R^2/2D$), equation (51) gives $\psi(q) = \exp(-Dq^2\Delta)$ as expected for unbounded diffusion; in the long time limit ($\Delta \gg R^2/2D$), $\psi(q) = \exp(-q^2 R^2/5)$. Comparison of these results suggests that the effective diffusion coefficient in the long time limit is $D_{\text{eff}} = R^2/5\Delta$. This turns out to be precisely the mean square displacement $\langle Z^2 \rangle$ divided by 2Δ . The exact solution for $\psi(q)$ in the long time limit obtained by adapting results from the literature of heat diffusion is

$$\psi(q) = 9[qR \cos(qR) - \sin(qR)]^2 / (qR)^6 \quad (53)$$

The long time limit of equation (51) agrees with exact result for small values of qR and the deviation is only 0.29% at $qR = 1$.

It is instructive to investigate the long time limit in more detail. If the fluid has the initial density distribution $\rho(z_0)$, in the limit $\Delta \rightarrow \infty$ we expect that $P(z_0 | z_0 + Z)$ will equal $\rho(z_0 + Z)$. Therefore, the average propagator can be written as

$$\bar{P}(Z, \infty) = \int \rho(z_0) \rho(z_0 + Z) dz_0 \quad (54)$$

Figure 14 Echo amplitudes versus q^2 for pore glass. The data sets were obtained with $\Delta = 20$ (■), 40 (●), 70 (▲), and 110 (◆) ms. (q in this figure is defined as $1/\Delta$)⁷⁰

and $\bar{P}(Z, \infty)$ is just the autocorrelation function of the molecular density or the convolution of the density with itself. It is also easy to show that equation (45) takes the form

$$\psi_\infty(q) = \left| \int \rho(z_0) \exp(-iqz_0) dz_0 \right|^2 \quad (55)$$

Equations (45) and (54) show that the inverse Fourier transform of the echo intensity provides an image of the autocorrelation function of the density in real space.^{69,70} This is the origin of diffraction-like effects in NMR diffusion studies, an idea that has led to a powerful method for the investigation of the structure of porous materials. For example, a 'pore glass' consisting of water in the presence of monodisperse spheres gives the echo intensities versus q shown in Figure 14.⁷⁰ At short times there is little indication that a water molecule samples more than one pore, while at longer times the diffraction effect resulting from neighboring pores is clearly visible. A Fourier transformation of an echo curve gives an image of the autocorrelation function. Note that this type of imaging gives resolution several orders of magnitude higher than MRI, since intensity is provided by the entire sample rather than a small voxel; but the information is limited to average features of local structure rather than positions of individual molecules in space.

Other important restricted diffusion problems include motion near an attracting center, diffusion in the presence of permeable walls and surface relaxers, inhomogeneous initial magnetization, and the effect of surface to volume ratios on the time dependence of the average propagator. These topics have been reviewed elsewhere,²⁵ except for the last one involving microgeometry and surface relaxation, a topic of considerable current interest in connection with the determination of pore size distributions.⁷¹⁻⁷³

7 ANISOTROPIC DIFFUSION

Anisotropic environments are found in organized phases such as liquid crystals and zeolite crystallites. The description of diffusion in such systems requires the diffusion tensor $\mathbf{D}_{\alpha,\beta}$ in place of the scalar coefficient D . As a consequence, the flux defined in equation (1) depends on orientation and the right-hand side of equation (4) becomes $-\nabla \cdot \mathbf{D} \cdot \nabla P(\mathbf{r}_0|\mathbf{r}, t)$. The attenuation factors have the same forms as previously found except that $g^2 D$ is replaced by $\mathbf{g} \cdot \mathbf{D} \cdot \mathbf{g}$. Therefore, if D_x , D_y , and D_z are defined as the principal values of the diffusion tensor the attenuation factor has the form

$$\psi(\theta, \phi) = \exp[-q^2 (D_x \cos^2 \phi \sin^2 \theta + D_y \sin^2 \phi \sin^2 \theta + D_z \cos^2 \theta) \Delta] \quad (56)$$

where θ and ϕ indicate the orientation of the gradient with respect to the principal axes of the diffusion tensor. For an axially symmetric diffusion tensor with $D_x = D_\perp$ and $D_z = D_\parallel$, we find that the mean square displacement in the direction of the gradient is proportional to $D_\parallel \cos^2 \theta + D_\perp \sin^2 \theta$. This type of treatment is appropriate for D_2O partially oriented in the lamellar phase of potassium palmitate/ D_2O .⁷⁴ In this system water diffusion is relatively unrestricted parallel to the bilayers but is limited in the direction of the director.

Unfortunately, the organized systems of interest for PFG-NMR studies are likely to present problems because of severe dipolar and quadrupolar broadening. Both quadrupolar⁷⁵ and solid echoes⁷⁶ may be useful replacements for the Hahn echo in such cases. Also, a Waugh-type line-narrowing sequence, modified to permit refocusing in the presence of gradient pulses, has been used to measure the anisotropy of a diffusion tensor of liquid crystal molecules in smectic-A and smectic-C phases.⁷⁷ These and other examples of measurement of anisotropic diffusion have recently been reviewed by Callaghan.²⁵

8 CHEMICAL EXCHANGE INVOLVING DIFFUSING MOLECULES

Chemical rate processes are detected by NMR when nuclei exchange between sites characterized by different spin Hamiltonians.⁷⁸ It is also possible that the sites will have similar spin Hamiltonians but will differ in hydrodynamic properties. In such cases the one-dimensional NMR spectrum is unaffected by exchange, but diffusion measurements may reveal the exchange process and permit it to be studied. Examples include: (i) association equilibria in which molecules diffuse freely or in association with larger, more slowly diffusing particles; and (ii) samples composed of subregions that are characterized by different numbers of spins and different diffusion coefficients.

Consider an FT-PFG-NMR experiment of the SE or STE type on a sample in which nuclei in various 'exchanging' sites all contribute to the same NMR line. In the slow exchange limit where exchange between sites is unlikely during the diffusion time Δ the signal amplitude can be described by a sum of exponentials as shown in equation (38). At the other extreme where many exchanges occur during Δ , a single exponential decay is found with a weighted average diffusion

coefficient. For intermediate exchange rates in the absence of strong spin coupling a simple theory of exchange, based on Bloch equations with diffusion and exchange terms, can be used to describe the evolution of longitudinal magnetization during the diffusion sensitive time interval $T = \Delta$ with $\tau, \delta \ll \Delta$. In this formulation the ‘on resonance’ magnetization $M_n(r, \Delta)$ for the n th species with spatial coordinates r is described by

$$\frac{dM_n(r, T)}{dT} = -\frac{1}{T_{1n}}M_n(r, T) - \nabla \cdot \mathbf{J}_n(r, T) + \sum_m K_{nm}M_m(r, T) \quad (57)$$

where the rate constants are given by $k_n = -K_{nn}$ and $k_{nm} = K_{nm}$. The flux $\mathbf{J}_n(r, T)$ is defined by

$$\mathbf{J}_n(r, T) = -D_n \nabla M_n(r, T) + M_n(r, T) \mathbf{v}_n(r, T) \quad (58)$$

where D_n and $\mathbf{v}_n(r, T)$ are the diffusion coefficient and velocity for the n th species, respectively. The calculation of the signal is simplified by taking the spatial Fourier transform of equation (57) to obtain

$$\frac{dM_n(q, T)}{dT} = (i\Omega_n - R_n)M_n(q, T) + \sum_m K_{nm}M_m(q, T) \quad (59)$$

where

$$M_n(q, T) = \int \exp(-i\mathbf{q} \cdot \mathbf{r}) M_n(r, T) d\mathbf{r} \quad (60)$$

Here $R_n = 1/T_{1n} + D_n q^2$ is a relaxation term, and $\Omega_n = \mathbf{q} \cdot \mathbf{v}_n$ describes the change in phase angle that results from flow, but for this discussion $1/T_{1n}$ and Ω_n are neglected. These equations and their solutions in special cases have been discussed by Kärger et al.,⁶⁰ and similar equations have been derived and studied for nuclear magnetic relaxation in multiple phase systems.⁷⁹

Most attention has been focused on the two-site exchange case that can be solved exactly. The fast and slow exchange limits can be recovered from the solutions and useful simple equations can be derived for special cases, but in general one must resort to numerical solutions. Special problems may arise in the application of the exchange model to porous systems since the transport processes may not be adequately described by equation (59), samples may not be sufficiently uniform in properties including spin relaxation rates, and susceptibility differences may distort local magnetic fields. However, exchange in liquids is free of such complications and should be well described by equation (59).

Chemical exchange in liquid mixtures is of interest in connection with DOSY.⁵⁴ In order to simulate diffusion spectra with exchange, the ILT of $M_n(q, T)$ must be obtained. In the two-site case the inversion can be performed analytically, and whenever equations are available for $M_n(q, T)$ the Fourier transform method (q^2 replaced with $i\omega$) can be used to obtain the ILT. The important quantity is the mean number of exchanges N that occur during the diffusion time T . In the slow exchange limit ($N \ll 1$) the diffusion spectrum consists

of delta functions at the various diffusion coefficients, and as the exchange rate increases the spectrum evolves into a single Gaussian peak centered on the average diffusion coefficient. For example, if spins exchange between two sites (A and B) with populations p_A and p_B and diffusion coefficients D_A and D_B , respectively, the peak is centered at $\langle D \rangle = p_A D_A + p_B D_B$. The distribution of diffusion rates results from the sequences of N exchanges that occur during T and the fraction of the time that a spin occupies each site. A simple calculation for $N \gg 1$ of the number of independent sequences associated with each diffusion coefficient gives a Gaussian distribution with the square deviation $\sigma^2 = \Delta D^2 p_A(1 - p_A)/N$ where $\Delta D = D_A - D_B$. Therefore, the width of the distribution depends on the exchange rate and offers the possibility of measuring this rate.

The fast and slow exchange limits are frequently encountered and recognized, but the intermediate exchange region is difficult to identify. The amplitude of the diffusion spectrum is low in the intermediate region, and as T/N increases the linewidth decreases and becomes difficult to measure. It is also difficult to distinguish between polydispersity and exchange broadening. However, the diffusion time T can be varied, and it may be possible in some cases to determine exchange rates by means of PFG-NMR. In fact, plots of the attenuation factor Ψ versus q^2 have been used in special cases to estimate the mean lifetime in a site.⁶⁰ But it should be clear that measurements of diffusion coefficients in the slow and fast limits give no information about exchange rates.

9 LARGE GRADIENTS AND THE MEASUREMENT OF SMALL DISPLACEMENTS

The measurement of small diffusion coefficients ($D \leq 10^{-11} \text{ cm}^2 \text{ s}^{-1}$) requires large values of the ‘scattering vector’ $\mathbf{q}$. Typically this is accomplished by increasing the amplitude of the gradient pulses. Modern gradient drivers for use with high-resolution spectrometers deliver 20–50 A for durations of a few milliseconds with pulse area matching to 10 ppm.⁴² The gradient coils, either Maxwell pairs or quadrupolar coils, then produce gradients of a few hundred gauss per centimeter.^{80,81} Much higher gradients have been reported, but usually at the cost of imperfect matching. However, even at the lower levels the pulsed gradient systems suffer from joule heating, vibrations, and pulse induced eddy currents in the metal components of the probe and neighboring magnet structures. Each of these problems can be minimized by special probe designs, but still the useful limit for stable gradient pulses appears to be approximately 10^3 G cm^{-1} in a narrow bore (5 cm) solenoid.

One way around the problem of gradient mismatch and sample motion is to accept phase variation from experiment to experiment and to correct the acquired data. A scheme to do this is called modulus addition using spatially separated echo spectroscopy (MASSEY), and the idea is as follows.⁸² A phase error resulting from gradient mismatch means that the magnetization helix is not exactly unwound at the echo time. Therefore, if the echo is read out in the presence of a small read gradient g_r , a coherent superposition will occur in the vicinity of the expected echo center. One should then Fourier transform the echo with respect to $\gamma g_r t$, where t is

measured from the beginning of the read gradient, and use the modulus spectrum to measure the echo amplitude. The procedure of Fourier transformation prior to signal averaging permits displacements in the range of 1–10 nm to be measured, but does lead to a loss in the signal-to-noise ratio.

In a very different approach Kimmich et al.⁸³ have reported diffusion experiments in the fringe field of a superconducting magnet. Gradients of up to 42 T m⁻¹ were obtained in a 4.7 T, 40 cm bore solenoid, and consistent results have been obtained in narrow bore solenoids. Thus, gradients of extremely high stability are obtained without heating, vibrations, and eddy currents. The supercon fringe field (SFF) experiment is remarkably easy to perform in any spectrometer system since one only needs the amplifier, receiver, and probe for the appropriate frequency in the fringe field. However, in its original form the SFF experiment has two major disadvantages. First, all frequency resolution is lost since the signal is acquired in the presence of the gradient. This is a serious loss, but useful information can still be obtained for specially selected systems. We note that successful experiments have been performed on polymer solutions and melts.⁸⁴ Second, the frequency gradient is approximately 2 MHz mm⁻¹, and a 1 μ s rf pulse only excites a layer 0.5 mm thick. This results in very poor filling factors and small signal-to-noise ratios.

Both SE or STE diffusion experiments are easy in the fringe field, but the STE experiment is more flexible. As illustrated in Figure 3, the gradient in the STE experiment is only effective for phase encoding and decoding during the time intervals τ_1 after the first and third rf pulses, and the result is identical to a pulsed gradient experiment with pulses of duration $\delta = \tau_1$. An estimate of the lowest accessible diffusion coefficient $D_{\min}$ can be made by demanding that the attenuation caused by diffusion be equal to that resulting from relaxation. The result of this calculation is

$$D_{\min} \simeq \frac{1}{\gamma^2 g^2} \frac{1}{\delta^3 (2/3 + T/\delta)} \left(\frac{T}{T_1} + \frac{2\delta}{T_2} \right) \quad (61)$$

If τ_1 and T are of the order of T_2 and T_1 , respectively, and $g = 42$ T m⁻¹, equation (61) gives $D_{\min} \approx 2 \times 10^{-20} / (T_1 T_2^2)$ in m² s⁻¹. An improved STE experiment that permits the effective gradient duration to be varied without affecting relaxation is shown in Figure 15.⁸⁵ The introduction of 180° pulses in the encode and decode intervals partially refocuses the magnetization and cancels part of the effective gradient.

While the gradient amplitudes achieved in SFF are accessible with pulsed field gradients, the freedom from complications

Figure 15 The five pulse STE sequence for SFF experiments. The effective gradient for encoding and decoding spatial positions has the duration δ ⁸⁵

and the absence of rise and decay times for gradient pulses makes SFF a very powerful technique. The shortcomings mentioned above are already being addressed. For example, small excitation volumes can be used to advantage by exciting nonoverlapping slices without having to wait for T_1 recovery. Also, shaped rf pulses can be used to permit different pulse lengths while maintaining the same bandwidth. The loss of resolution appears to be intractable unless the sample can be moved into a homogeneous field for data acquisition. A shuttle system of the type developed for zero field spectroscopy can satisfy this requirement for samples with $T_1 > 100$ ms.

10 DATA ANALYSIS AND POLYDISPERSITY

Data sets from PFG-NMR (SE and STE) experiments are usually in the form of a signal versus q^2 or $q^2 \Delta$. For a monodisperse sample a single exponential decay as shown in equations (27) and (29) is expected. The logarithm of the signal can be fit as a linear function, but this emphasizes noise as the signal approaches zero and complicates the problem of proper weighting factors for the data points. It is better to use a nonlinear regression method to fit the exponential function directly. The Levenberg–Marquardt method is popular for this purpose.⁸⁶

The problem may be much more difficult when more than one diffusing species contributes to the observed decay. The discrete and continuous distributions of diffusion coefficients as described by equations (38) and (42), respectively, were discussed in connection with automated analysis to obtain diffusion ordered spectra. The same analysis problem has played a major role in the development of dynamic light scattering and the extensive reviews can be found in the literature of DLS. Highly recommended sources are the analysis chapters in the monographs by Schmitz⁸⁷ and Chu⁴ and the recent review by Štěpánek.⁸⁸ In general, the analysis problem is intractable. Exact answers cannot be extracted from the data and sometimes a wide variety of parameter sets fits the data within experimental error. There are, of course, some special cases where accurate answers can be determined easily or where the limited information required to characterize a distribution can be measured quite directly.

The discrete two-component decay, i.e. equation (38) with $N_\lambda = 2$, requires two decay constants, two amplitudes, and perhaps a baseline. Analysis is easy only when the decay constants differ by a large factor, the amplitudes are comparable, and the signal-to-noise ratio is high. When the answers are not obvious from a log plot, nonlinear regression procedures are sometimes used, but the latter do not provide a reliable procedure for multicomponent exponential decays, even when the number of components is known. The problem is that initial guesses of the parameters are required, and these may determine the outcome. For objective conclusions about the answers or even about the intractability of the problem, it is essential that the analysis not be biased by the user. A reasonable alternative is to use the program DISCRETE, which determines initial parameters by a Fourier method and then applies the least-squares method.^{48,49} The program SPLMOD is similar but faster, and it permits the simultaneous analysis of multiple data sets.^{50,51}

The continuous case requires, in principle, an ILT to determine the distribution of diffusion coefficients. There

appears to be only one simple case. If the distribution is unimodal and the distribution is narrow, a direct cumulant analysis may suffice. This method, introduced by Koppel,⁸⁹ is based on the expansion of the exponential function in equation (42) about the average decay constant $\langle\lambda\rangle$. The result is

$$G(s) = \exp \left[-\langle\lambda\rangle s + \frac{\mu_2}{2!} s^2 - \frac{\mu_3}{3!} s^3 + \frac{(\mu_4 - 3\mu_2^2)}{4!} s^4 + \dots \right] \quad (62)$$

where

$$\langle\lambda\rangle = \int_0^\infty \lambda g(\lambda) d\lambda, \quad \mu_n = \int_0^\infty (\lambda - \langle\lambda\rangle)^n g(\lambda) d\lambda \quad (63)$$

A fit of equation (62) to the experimental data set, $G(s)$ versus s , by means of nonlinear regression typically yields $\langle D \rangle$ and $\mu_2 = (\langle D^2 \rangle - \langle D \rangle^2) / \langle D \rangle^2$ with reasonable accuracy. The higher moments are less reliable. The ratio $\mu_2 / \langle D \rangle^2$ is commonly used as an index of polydispersity; but, when this ratio exceeds 0.3, equation (62) is not justified.

When broad or multimodal distributions are expected, general ILT analyses are required. Seven schemes have recently been compared by Štěpánek.⁸⁸ The most widely used methods are constrained regularization (CONTIN), nonlinear regularization (REPES), maximum entropy (MEM), and exponential sampling. Prospective users should study the reviews to become familiar with the types of artifacts characteristic of these methods. Also, it is strongly advised that simulated data similar to the data of interest be analyzed to obtain experience with limitations of the analyses. When noise is present, the information content of the PFG-NMR data sets is simply not sufficient to provide an exact image of the distribution. One must be satisfied with a reasonable estimate rather than no solution at all.

11 MASS AND SIZE DISTRIBUTIONS FROM NMR DIFFUSION DATA

The PFG-NMR data set $G(s)$ collected at a specific chemical shift for a polydisperse sample has the form (see Section 4.1):

$$G(s) = \int_0^\infty g_\kappa(\kappa) \exp[-D(\kappa)s] d\kappa \quad (64)$$

If $\kappa = D$ then $D(\kappa) = D$ and equations (64) and (42) are identical, but equation (64) is more general since κ may represent another molecular parameter of interest, e.g. molecular radius R or molar mass M . For example, the ILT of $G(q^2)$ gives $g_D(D)$, but $g_M(M)$ the distribution function for molar mass may be of interest. Equation (64) indicates that the normalized distribution for molar mass is given by $g_M(M) = g_D(D) |dD/dM|$.⁴ For linear polymers this transformation can be carried out with the assumption that $D(M) = KM^{-\alpha}$, where K is a constant. Here α ranges from 0.6 for dilute solutions to 2.0 for melts when the ‘reptation’ model holds.⁹⁰ However, this treatment ignores possible spin relaxation effects that may depend on the mass. In general, the distribution functions should include a relaxation factor, e.g. $g_M(M)$ becomes $A_0(M)g_M(M)$, where $A_0(M)$ depends

on T_1 and T_2 . The small molecules tend to have longer relaxation times and, therefore, contribute disproportionately to the measured diffusion coefficient. Therefore, the neglect of $A_0(M)$ leads to higher apparent diffusion coefficients.

Unfortunately, equation (64) is not always appropriate. A number of experimental studies of polymer mixtures have found essentially exponential attenuation curves and, therefore, much less indication of polydispersity than predicted.^{91,92} The important point is that equation (64) only holds when the diffusion rate of a polymer molecule is independent of the lengths of the neighboring polymer chains.⁹³ This condition is satisfied in very dilute solutions⁹⁴ and in the melts when diffusion can be described by the ‘reptation’ model.⁹⁰ Otherwise, little information can be obtained from $G(s)$ about $g_M(M)$. The averaging effect resulting from interactions with neighbors has been called ‘microscopic’ averaging.⁹²

Another aim of diffusion studies is to size particles, i.e. to determine $g_R(R)$. As shown above $g_R(R)$ can be obtained from $g_D(D)$ if the relation between D and R is known. For spherical particles equation (7) with appropriate corrections for volume fraction can be assumed and $g_R(R)$ can be derived. However, this distribution is weighted by the number of nuclei contributing to the signal, i.e. the number of nuclei with diffusion coefficients in the range D to $D + dD$. The number of particles in the range D to $D + dD$ may be the quantity of interest, and these distributions can be related if the number of nuclei can be determined as a function of R . For example, for vesicles the number of molecules in the bilayer increases roughly with R^2 while the number of molecules entrapped in the aqueous cavity increases with R^3 .⁵⁶ Therefore, the unnormalized distribution function for the number of nuclei associated with radii in the range R to $R + dR$ is proportional to $R^n g_R(R)$, with $n = 2$ or 3 depending on the source of the signal. Also, the relaxation factor $A_0(R)$ is important here since T_2 is short for bilayer protons and depends on R through the rotational correlation time. The result is that the uncorrected diffusion coefficients determined from bilayer signals are much higher than those obtained with signals from molecules entrapped in the aqueous cavity. In addition, the microscopic averaging effect mentioned above may reduce the effect of polydispersity on the observed signals. All of these problems are compounded because data inversion methods often yield inaccurate estimates of $g_R(R)$.

Similarities between NMR and DLS analyses have been noted, but it should be kept in mind that different kinds of averaging processes are involved. When relaxation can be ignored NMR intensities depend on the number of nuclei involved in the resonance and this number may be proportional to the molecular weight of a molecule, the volume of an entrapped fluid, etc. In DLS the intensity is proportional to the number of scatterers, but each scatterer is weighted by the square of the number of electrons. In some cases the number of electrons is proportional to the mass and to the volume of a molecule. This is the origin of the well-known rule that scattering from a particle is proportional to the square of its volume. Therefore, in the limit of infinite dilution where tracer and mutual diffusion coefficients are equal, NMR and DLS may still give different average diffusion coefficients for polydisperse samples. Also, as a practical matter, PFG-NMR data sets usually have fewer points and lower signal-to-noise ratios than data sets obtained in DLS.

12 LITERATURE SOURCES FOR NMR DIFFUSION MEASUREMENTS

The most complete, up-to-date treatment of translational dynamics and its study by NMR is found in the book by Callaghan.²⁵ The experimental and theoretical aspects of diffusion in liquids are treated in the monograph by Tyrrell and Harris,² and Crank's book¹ is still the standard reference for the mathematics of diffusion. The principles and applications of PFG-NMR have been reviewed by Kärger et al.,⁶⁰ and Stilbs³⁹ has provided a detailed review of FT diffusion studies. NMR studies of diffusion in polymer systems have been reviewed by von Meerwall.^{95,96} Wade⁹⁷ has reviewed lateral diffusion in lipids including NMR measurements, and Chachaty⁹⁸ has reviewed NMR relaxation and diffusion studies of micellar solutions. Molecular diffusion in NMR imaging has been reviewed by Le Bihan⁹⁹ (note that the references in this review incorrectly replace *Phys.* with *Physiol.* in several places). Multiple-quantum methods including sensitivity to gradients and use in diffusion studies have been reviewed by Norwood.¹⁰⁰

1 INTRODUCTION

The *filter diagonalization method* (FDM) is a linear algebraic method of spectral analysis of time signals and, in particular, NMR signals, that is meant to compliment or replace Fourier Transform (FT) spectral analysis. One-dimensional (1D) FDM and its multi-dimensional (mD) extensions exist. Related techniques that have emerged from the FDM are the *regularized resolvent transform* (RRT) and *extended fourier transform* (XFT). Most results reported here can be found in Refs.^{1–18} We attempt to present FDM critically, emphasizing both its advantages and drawbacks. FDM is not always advantageous, but for many kinds of spectra it can be. Some unsolved challenges, either conceptual or computational, associated mostly with the mD FDM, are identified. The first sections lay the mathematical underpinnings, while the latter sections show applications and highlight experimental considerations.

1.1 Important Notations

A linear operator is identified by a cap: $\hat{A}$. In the expression $|b\rangle = \hat{A}|c\rangle$ a vector $|c\rangle$ from a linear space is mapped to a vector $|b\rangle$ from the same space. $\langle c|$ defines a dual vector to $|c\rangle$ and $\langle c|b\rangle = \langle b|c\rangle$, complex symmetric (i.e., no complex conjugation) inner product between the two vectors $|c\rangle$ and $|b\rangle$. Bold characters, as $\mathbf{A}$ or $\mathbf{C}$ are used for matrix representations of linear operators or vectors. Their elements are then defined using the following notations: $[\mathbf{A}]_{mn}$ or $[\mathbf{C}]_n$. $\mathbf{A}^T$ is a transpose of matrix $\mathbf{A}$, while $\mathbf{A}^\dagger$, is its adjoint (transposed and complex conjugated) matrix. Almost all variables are *complex* numbers, including ω_k , d_k , etc., although time variables t , τ , etc., are real.

2 FORMULATION OF THE PROBLEMS

2.1 1D Spectral Analysis

Consider a finite complex valued 1D time signal $c_n := c(n\tau)$, ($n = 0, \dots, N-1$), that has been sampled instantaneously on an equidistant discrete set of time points. By the *Fourier spectral estimation* problem we mean estimating the infinite time discrete Fourier transformation (DFT) of c_n :

$$I(s) := \sum_{n=0^+}^{\infty} c_n z^{-n} := \sum_{n=0}^{\infty} \left(1 - \frac{\delta_{n0}}{2}\right) c_n z^{-n} \quad (1)$$

using the finite data set. Here $z = e^{-i\tau s}$; the ‘shortcut’ $\sum_{n=0^+}$, meaning that the first term in the sum is multiplied by 1/2, will be used throughout the article. The latter corrects an error due to the discretization of the half-line Fourier integral

$$I_0(s) := \int_0^{\infty} c(t) e^{its} dt = \lim_{\tau \rightarrow 0} \tau I(s) \quad (2)$$

The 1D *parameter estimation* or *harmonic inversion problem* (HIP), by contrast, corresponds to the *fitting* of the finite data set c_n by the form

$$c_n = \sum_{k=1}^K d_k u_k^n \quad (3)$$

with $u_k = e^{-i\tau\omega_k}$. The unknown parameters are the complex poles u_k (or, alternatively, the frequencies ω_k) and complex amplitudes d_k . It is not obvious that a linear algebraic solution of the HIP exists as at first glance it requires a nonlinear least squares fit.

Once a *line list* $\{u_k, d_k\}$ is obtained, one can construct an *ersatz spectrum*

$$I(s) = \sum_k d_k \left\{ \frac{z}{z - u_k} - \frac{1}{2} \right\} \quad (4)$$

which estimates the DFT spectrum (1). Note that, although the infinite Fourier series (1) converges only if all poles u_k satisfy $|u_k| \leq 1$, a sensible and stable result can be obtained using equation (4), even when this is not the case. Moreover, the stability is maintained only if one does not exclude or modify the ‘unphysical’ entries with u_k far outside the unit circle. It is recommended though to flip the poles with $|u_k| > 1$ which are close to the unit circle, i.e., $|u_k| \sim 1$, using $u_k \rightarrow u_k/|u_k|^2$ before inserting into equation (4). This eliminates sign problems caused by inaccurate width estimation for very narrow peaks when using short data records.

Note also that, if the sampling theorem is satisfied, there is no significant difference in the appearance of the DFT spectrum (1) and the integral half-line FT integral (2), except for very broad lines (i.e., with line widths $|\text{Im } \omega_k|$ comparable to the spectral width $\text{SW} = 1/\tau$). The dispersion-mode wings of these lines, in particular, alias in the DFT case. Practically speaking the form (4) is significantly more stable than its integral counterpart¹⁶

$$I_0(s) = \sum_k \frac{id_k}{s - \omega_k} \quad (5)$$

and is what is used in practice.

2.2 mD Spectral Analysis

Consider a general complex valued mD time signal $c_{n_1, \dots, n_D} := c(n_1 \tau_1, \dots, n_D \tau_D)$, defined on an equidistant rectangular time grid of size $N_{\text{total}} = N_1 \times \dots \times N_D$.

The mD Fourier spectral estimation problem then becomes that of estimating the infinite sum,

$$I(s_1, \dots, s_D) = \sum_{n_1=0^+}^{\infty} z_1^{-n_1} \dots \sum_{n_D=0^+}^{\infty} z_D^{-n_D} c_{n_1, \dots, n_D} \quad (6)$$

with $z_l = e^{-in_l \tau_l s_l}$, ($l = 1, \dots, D$).

One possible and, probably, most desirable formulation of the mD HIP is

$$c_{n_1, \dots, n_D} = \sum_{k=1}^K d_k u_{1k}^{n_1} \dots u_{Dk}^{n_D} \quad (7)$$

where the unknown parameters are the complex amplitudes d_k and frequencies ω_{lk} with $u_{lk} = e^{-in_l \tau_l \omega_{lk}}$, ($l = 1, \dots, D$). These parameters, once computed, can be used to construct various representations of the mD spectrum, such as that defined by equation (6),

$$I(s_1, \dots, s_D) = \sum_k d_k \prod_{l=1}^D \left\{ \frac{z_l}{z_l - u_{lk}} - \frac{1}{2} \right\} \quad (8)$$

or a more useful mD absorption-mode spectrum

$$A(s_1, \dots, s_D) = \text{Re} \sum_k d_k \prod_{l=1}^D \text{Re} \left\{ \frac{z_l}{z_l - u_{lk}} - \frac{1}{2} \right\} \quad (9)$$

Unfortunately, the present versions of FDM can provide a sensible mD line list only when the data well approximates the form equation (7) with high signal-to-noise ratio (SNR). We will refer to such cases as the *well defined HIP*. However, for a poorly defined mD HIP various spectral representations, including absorption-mode spectra, can still be constructed in the FDM framework, but by carefully avoiding the solution of equation (7).

3 PARAMETER AND SPECTRAL ESTIMATION BY 1D FDM

The commonly used starting point in most linear algebraic approaches is the autoregression (AR) assumption, which in 1D case reads

$$c_n = \sum_{p=1}^K a_p c_{n-p} \quad (10)$$

This assumption is equivalent to equation (3), but requires that one solves for the auxiliary prediction coefficients a_p . These are not, however, the ultimate quantities of interest. To

recast the spectral analysis problem into the linear algebraic framework in FDM one assumes the existence of an auxiliary quantum dynamical system with a complex symmetric evolution operator $\hat{U}$ of rank K and a fictitious state Φ , so that the data may be represented in the form of the autocorrelation function¹

$$c_n = (\Phi | \hat{U}^n | \Phi) \quad (11)$$

It can be shown that the three assumptions (3), (10) and (11) are equivalent, although the latter leads directly to the solution of either HIP or the spectral estimation problem and is therefore more economical. For example, assuming $\hat{U}$ is diagonalizable,

$$\hat{U} \Upsilon_k = u_k \Upsilon_k, \quad (k = 1, \dots, K) \quad (12)$$

we get equation (3) with

$$d_k = (\Phi | \Upsilon_k)^2 (\Upsilon_k | \Upsilon_k)^{-1} \quad (13)$$

which suggests that the HIP is equivalent to a matrix eigenvalue problem arising from equation (12). This can be shown by using $N = 2M$ and implementing the Krylov basis

$$\Phi_n := \hat{U}^n \Phi, \quad (n = 0, \dots, M-1)$$

We can now define the evolution operator matrix $\mathbf{U}_1$, the overlap matrix $\mathbf{U}_0$ and the signal vector $\mathbf{C}$ and evaluate them in terms of the signal points c_n utilizing the assumption (11):

$$[\mathbf{U}_p]_{nm} := (\Phi_n | \hat{U}^p | \Phi_m) = c_{n+m+p}$$

$$[\mathbf{C}]_n := (\Phi | \Phi_n) = c_n$$

By expanding the eigenfunctions, $\Upsilon_k = \sum_n [\mathbf{B}_k]_n \Phi_n$, we obtain the generalized eigenvalue problem

$$\mathbf{U}_1 \mathbf{B}_k = u_k \mathbf{U}_0 \mathbf{B}_k \quad (14)$$

for the unknown eigenvalues u_k and eigenvectors $\mathbf{B}_k$. If $M \geq K$, with exact arithmetic equation (14) then yields the exact solution of the HIP (3) with

$$d_k = (\mathbf{C}^T \mathbf{B}_k)^2 (\mathbf{B}_k^T \mathbf{U}_0 \mathbf{B}_k)^{-1} \quad (15)$$

The latter result is derived from equation (13). This and similar expressions have been first derived in the FDM framework.^{1,2} Note though that equation (14) was used previously¹⁹ to estimate the parameters u_k .

Interestingly, once the data arrays $\mathbf{U}_0$, $\mathbf{U}_1$ and $\mathbf{C}$ are obtained in a suitable representation, the DFT spectrum $I(s)$ can be estimated *directly*, avoiding the use of the spectral parameters u_k and d_k and hence the solution of the generalized eigenvalue problem. This is done by first inserting equation (11) into equation (1) and evaluating the geometric series,

$$I(s) = (\Phi | \left(\frac{1 - \hat{U}}{z} \right)^{-1} | \Phi) - \frac{c_0}{2}$$

and then using the above matrix representations

$$I(s) = \mathbf{C}^T \mathbf{R}^{-1} \mathbf{C} - \frac{c_0}{2}, \quad \mathbf{R} = \frac{\mathbf{U}_0 - \mathbf{U}_1}{z} \quad (16)$$

In the noiseless case for $M = K$ the spectral estimate (16) is exact. For $M \geq K$ the matrix pencil $\mathbf{R}$ is singular and the evaluation of the resolvent $\mathbf{R}^{-1}$ requires a *regularization*. For example, one can implement the *singular value decomposition* (SVD) of $\mathbf{R}$ and then evaluate the inverse in the range subspace of $\mathbf{R}$. This still gives the exact result for the noiseless case. In practice $\mathbf{R}$ is never exactly singular, but could be ill-conditioned, so that regularization is most definitely required. In this case truncated SVD (as described above) is not recommended. Instead, a rather more robust regularization scheme can be implemented,^{14,17} such as the Tikhonov regularization,²⁰ that requires solution of a Hermitian linear least squares problem at each value of frequency s :

$$I(s) \approx \mathbf{C}^T \mathbf{X} - \frac{c_0}{2}, \quad (\mathbf{R}^\dagger \mathbf{R} + q^2) \mathbf{X} = \mathbf{R}^\dagger \mathbf{C} \quad (17)$$

where q is a real regularization parameter that controls the noise and artifact suppression. Bigger values of q lower the resolution, but lead to more uniform spectral estimates, rather like line broadening in FT analysis. The spectral estimate (17) was derived in Ref.¹⁴ and named RRT (Regularized Resolvent Transform). In a related technique XFT the spectrum is estimated by partitioning the infinite DFT sum (1) into a finite DFT over the measured data length and a correction term, which is evaluated using an RRT-type expression.¹⁷

3.1 Fourier Subspace Filtering

Solution of the $M \times M$ generalized eigenvalue problem (14) or the matrix inversion in equation (17) has $\sim M^3$ numerical scaling and is thus impractical. A Fourier basis has proven to be very efficient for such problems.^{1,2} A small Fourier subspace $\{\tilde{\Phi}_j\}$ of size $K_{\text{win}} \ll M$ is constructed by choosing K_{win} complex numbers on the unit circle $y_j = e^{-i\tau\varphi_j}$, ($j = 1, \dots, K_{\text{win}}$) and using

$$\tilde{\Phi}_j = \sum_{n=0}^{M-1} \left(\frac{\hat{U}}{y_j} \right)^n \Phi$$

where the tilde over vectors or matrices will denote the use of a Fourier basis. The results are not usually sensitive to the parameters of the basis as long as the points φ_j are chosen appropriately. In most cases an equidistant grid is effective, with spacing

$$\Delta\varphi = \frac{2\pi}{\aleph M\tau} \quad (18)$$

and adjustable parameter $\aleph \geq 1$ (e.g., one can use $\aleph = 1.2$). Since the basis is localized in the frequency domain, the diagonal elements of the matrices will dominate, and the off-diagonal elements will drop off as a sinc function. This allows an accurate solution of equation (14) or the spectral estimation in equation (17) in a small subspace, leading to numerically inexpensive linear algebra. A further gain may be achieved by using a multi-scale Fourier basis¹¹ with a non-uniform set of φ_j values, containing information about the entire spectrum rather

than just the spectral window. Note that filtering the *basis* is conceptually different than e.g., digital filtering of the *signal*. That is, the true signal is used to construct matrix elements, and then this matrix, which is potentially huge, is treated in a basis which allows diagonalization to proceed in a block-diagonal fashion, so that only a relatively small numbers of matrix elements need to be computed.

The matrix elements of the $K_{\text{win}} \times K_{\text{win}}$ square matrices $\tilde{\mathbf{U}}_1$ and $\tilde{\mathbf{U}}_0$ can be computed using²

$$\begin{aligned} [\tilde{\mathbf{U}}_p]_{jj'} &:= (\tilde{\Phi}_j | \hat{U}^p | \tilde{\Phi}_{j'}) \\ &= \hat{S} \sum_{\sigma=0,1} \frac{(-1)^\sigma (y_j/y_{j'})^M}{1 - y_j/y_{j'}} \sum_{n=\sigma M}^{(\sigma+1)(M-1)} y_j^{-n} c(n+p) \end{aligned}$$

where $\hat{S}$ defines symmetrization operator over the variables y_j and $y_{j'}$,

$$\hat{S}g(y_j, y_{j'}) = g(y_j, y_{j'}) + g(y_{j'}, y_j)$$

For $j = j'$ we have

$$[\tilde{\mathbf{U}}_p]_{jj} = \sum_{n=0}^{2M-2} y_j^{-n} (M - |M - n - 1|) c(n+p)$$

The state vector Φ in the Fourier basis is a $1 \times K_{\text{win}}$ column vector with elements

$$[\tilde{\mathbf{C}}]_j := (\tilde{\Phi}_j | \Phi) = \sum_{n=0}^{M-1} y_j^{-n} c_n$$

The generalized eigenvalue problem (14) in the Fourier basis now reads

$$\tilde{\mathbf{U}}_1 \tilde{\mathbf{B}}_k = u_k \tilde{\mathbf{U}}_0 \tilde{\mathbf{B}}_k \quad (19)$$

with the coefficients computed by

$$d_k = \left(\tilde{\mathbf{C}}^T \tilde{\mathbf{B}}_k \right)^2 \left(\tilde{\mathbf{B}}_k^T \tilde{\mathbf{U}}_0 \tilde{\mathbf{B}}_k \right)^{-1} \quad (20)$$

Defining the $K_{\text{win}} \times K_{\text{win}}$ matrix-pencil $\tilde{\mathbf{R}} = \tilde{\mathbf{U}}_0 - \tilde{\mathbf{U}}_1/z$ in the Fourier basis, the RRT spectral estimate becomes

$$I(s) \approx \tilde{\mathbf{C}}^T \tilde{\mathbf{X}} - \frac{c_0}{2}, \quad (\tilde{\mathbf{R}}^\dagger \tilde{\mathbf{R}} + q^2) \tilde{\mathbf{X}} = \tilde{\mathbf{R}}^\dagger \tilde{\mathbf{C}} \quad (21)$$

Since a small subspace, rather than the complete basis $\{\Phi_n\}$, is used, equations (19), (20) and (21) must be viewed as an approximation to equations (14), (15) and (17) with convergence parameter K_{win} . However, an acceptable convergence is usually achieved for sufficiently small sizes in the range $K_{\text{win}} \sim 10-100$. Moreover, in the Fourier basis, the matrices are much less ill-conditioned, which makes them easier to handle numerically.

4 mD FDM

Generalizing the 1D quantum ansatz (11) the mD signal is assumed to be generated by D commuting complex symmetric evolution operators $\hat{U}_l$, ($l = 1, \dots, D$):

$$c_{n_1, \dots, n_D} = (\Phi | \prod_{l=1}^D \hat{U}_l^{n_l} | \Phi) \quad (22)$$

Clearly, if all the operators $\hat{U}_l$ have the same rank K with nondegenerate eigenvalues u_{lk} and the corresponding eigenfunctions Υ_k , equation (22) yields equation (7) with the amplitudes $d_k = (\Phi | \Upsilon_k)^2 (\Upsilon_k | \Upsilon_k)^{-1}$. However, the assumption about the existence of a simultaneous basis $\{\Upsilon_k\}$ leads to numerical troubles.⁸ It turns out that it can be avoided by keeping only the requirement that $\hat{U}_l$ commute with each other. That is, we will label the eigenfunctions of $\hat{U}_l$ by l :

$$\hat{U}_l \Upsilon_{lk} = u_{lk} \Upsilon_{lk}, \quad (l = 1, \dots, D) \quad (23)$$

By inserting the quantum ansatz (22) into equation (6) and evaluating the product of D geometric sums, in analogy with equation (16), we get the resolvent representation of the mD DFT spectrum:

$$I(s_1, \dots, s_D) = (\Phi | \prod_{l=1}^D \left\{ \frac{z_l}{z_l - \hat{U}_l} - \frac{1}{2} \right\} | \Phi) \quad (24)$$

Now using $2M_l = N_l$ for $l = 1, \dots, D$ and representing everything in the Krylov basis $\Phi_{n_1, \dots, n_D} := \hat{U}_1^{n_1} \dots \hat{U}_D^{n_D} \Phi$ with total size $M_{\text{total}} = M_1 \times \dots \times M_D$, we can replace equation (23) by generalized eigenvalue problems with known data matrices $\mathbf{U}_l$ or, alternatively, obtain an mD RRT spectral estimate. However, as in the 1D case, it is advantageous to implement a Fourier basis. For the sake of simplicity, here we consider only the $D = 2$ case.

4.1 Fourier Basis: 2D Case

Let $\{\varphi_{1j}, \varphi_{2j}\}$ be a set of $K_{1\text{win}} \times K_{2\text{win}} = K_{\text{win}}$ grid points in a chosen 2D frequency window with spacings, given by equation (18), in each dimension. We can now define the Fourier basis using:

$$\tilde{\Phi}_j = \sum_{n_1=0}^{M_1-1} \sum_{n_2=0}^{M_2-1} \left(\frac{\hat{U}_1}{y_{1j}} \right)^{n_1} \left(\frac{\hat{U}_2}{y_{2j}} \right)^{n_2} \Phi$$

with $y_{lj} = e^{-i n_l \tau_l \varphi_{lj}}$, ($l = 1, 2$). The square complex symmetric matrices of $\hat{U}_1$, $\hat{U}_2$ and the identity operator (the overlap matrix) in this basis are defined by $\tilde{\mathbf{U}}_1$, $\tilde{\mathbf{U}}_2$ and $\tilde{\mathbf{U}}_0$, accordingly. To consolidate the expressions, three new data sets are defined:

$$c_{n_1, n_2}^{(0)} := c_{n_1, n_2}; \quad c_{n_1, n_2}^{(1)} := c_{n_1+1, n_2}; \quad c_{n_1, n_2}^{(2)} := c_{n_1, n_2+1}$$

The matrix elements of the U -matrices for both $y_{1j} \neq y_{1j'}$ and $y_{2j} \neq y_{2j'}$ can be computed by³

$$\begin{aligned} [\mathbf{U}_l]_{jj'} &= \hat{S}_1 \sum_{\sigma_1=0,1} \frac{(-1)^{\sigma_1} (y_{1j}/y_{1j'})^{M_1}}{1 - y_{1j}/y_{1j'}} \\ &\times \hat{S}_2 \sum_{\sigma_2=0,1} \frac{(-1)^{\sigma_2} (y_{2j}/y_{2j'})^{M_2}}{1 - y_{2j}/y_{2j'}} \\ &\times \sum_{n_1=\sigma_1 M_1}^{(\sigma_1+1)(M_1-1)} \sum_{n_2=\sigma_2 M_2}^{(\sigma_2+1)(M_2-1)} y_{1j}^{-n_1} y_{2j}^{-n_2} c_{n_1 n_2}^{(l)} \end{aligned}$$

where $\hat{S}_1$ and $\hat{S}_2$ define the symmetrization operators over the corresponding pairs of variables as, e.g.,

$$\hat{S}_1 g(y_{1j}, y_{1j'}) = g(y_{1j}, y_{1j'}) + g(y_{1j'}, y_{1j})$$

For $y_{1j} = y_{1j'}$ and $y_{2j} \neq y_{2j'}$ we have

$$\begin{aligned} [\mathbf{U}_l]_{jj'} &= \hat{S}_2 \sum_{\sigma_2=0,1} \frac{(-1)^{\sigma_2} (y_{2j}/y_{2j'})^{M_2}}{1 - y_{2j}/y_{2j'}} \\ &\times \sum_{n_1=0}^{2M_1-2} \sum_{n_2=\sigma_2 M_2}^{(\sigma_2+1)(M_2-1)} y_{1j}^{-n_1} y_{2j}^{-n_2} c_{n_1 n_2}^{(l)} \\ &\times (M_1 - |M_1 - n_1 - 1|) \end{aligned}$$

which can trivially be rewritten for the symmetric case of $y_{1j} \neq y_{1j'}$ and $y_{2j} = y_{2j'}$. For the case of both $y_{1j} = y_{1j'}$ and $y_{2j} = y_{2j'}$, i.e., the diagonal elements of the U -matrices, we have

$$\begin{aligned} [\mathbf{U}_l]_{jj} &= \sum_{n_1=0}^{2M_1-2} \sum_{n_2=0}^{2M_2-2} y_{1j}^{-n_1} y_{2j}^{-n_2} c_{n_1 n_2}^{(l)} \\ &\times (M_1 - |M_1 - n_1 - 1|)(M_2 - |M_2 - n_2 - 1|) \end{aligned}$$

We will also need the $1 \times K_{\text{win}}$ column vector:

$$[\tilde{\mathbf{C}}]_j = \sum_{n_1=0}^{M_1-1} \sum_{n_2=0}^{M_2-1} y_{1j}^{-n_1} y_{2j}^{-n_2} c_{n_1 n_2}$$

4.2 Regularization of the mD FDM: FDM2K

Armed with the above expressions, we can replace the eigenvalue problems for the effective evolution operators (23) by generalized eigenvalue problems with known matrices and unknown eigenvalues u_{lk} and eigenvectors $\mathbf{B}_{lk}$:

$$\tilde{\mathbf{U}}_l \tilde{\mathbf{B}}_{lk} = u_{lk} \tilde{\mathbf{U}}_0 \tilde{\mathbf{B}}_{lk}, \quad (l = 1, \dots, D) \quad (25)$$

Unfortunately, unlike the 1D case, unless we are dealing with a noiseless well-defined mD HIP, a straightforward numerical solution of these equations gives meaningless results. A meaningful solution may be obtained by implementing a truncated SVD in which one defines the effective range space of $\mathbf{U}_0$, e.g., by keeping the largest P singular values, and then reevaluates the U -matrices in this subspace. However, this type of regularization, as in the RRT case, is usually quite sensitive to the choice of P and requires a lot of fiddling

around. We have discovered empirically¹⁵ a much more robust regularization procedure, in which equation (25) is replaced by

$$\tilde{\mathbf{U}}_0^\dagger \tilde{\mathbf{U}}_l \tilde{\mathbf{B}}_{lk} = u_{lk} \left(\tilde{\mathbf{U}}_0^\dagger \tilde{\mathbf{U}}_0 + q^2 \right) \tilde{\mathbf{B}}_{lk}$$

with regularization parameter q . The effect of the regularization is similar to that in RRT in that the results depend fairly smoothly on q , eliminating the need for extensive fiddling. Even though expression (20) to compute the coefficients holds, in principle, in the mD case, it is very tricky to use and is avoided here. A more correct approach is to use the eigenvalues u_{lk} and eigenvectors B_{lk} to construct the mD spectrum:^{10,16}

$$I(s_1, \dots, s_D) = \sum_{k_1, \dots, k_D} d_{k_1, \dots, k_D} \prod_{l=1}^D \left\{ \frac{z_l}{z_l - u_{lk_l}} - \frac{1}{2} \right\} \quad (26)$$

with

$$d_{k_1, \dots, k_D} = \frac{\tilde{\mathbf{C}}^T \tilde{\mathbf{B}}_{1k_1} \tilde{\mathbf{B}}_{1k_1}^T}{\tilde{\mathbf{B}}_{1k_1}^T \tilde{\mathbf{U}}_0 \tilde{\mathbf{B}}_{1k_1}} \left(\prod_{l=2}^D \frac{\tilde{\mathbf{U}}_0 \tilde{\mathbf{B}}_{lk_l} \tilde{\mathbf{B}}_{lk_l}^T}{\tilde{\mathbf{B}}_{lk_l}^T \tilde{\mathbf{U}}_0 \tilde{\mathbf{B}}_{lk_l}} \right) \mathbf{C}$$

Clearly, equation (26) has somewhat different structure from the form of equation (8) as each combination ($u_{1k_1}, \dots, u_{Dk_D}$) gives a peak with the amplitude $d_{k_1, \dots, k_D}$, i.e., many more than one would expect. This is the price for avoiding the use of a simultaneous eigenbasis in equation (23). Numerically, though, most cross-amplitudes $d_{k_1, \dots, k_D}$ will vanish. Expression (26) appears much more stable and easier to use numerically than equation (8) in the case of degenerate eigenvalues u_{lk} or low SNR.

By analogy with equation (9) an absorption-mode mD spectrum can be constructed, even from a single phase-modulated data set, by replacing the complex (phase-twist) Lorentzians by the absorption-mode lineshapes in equation (26):

$$A(s_1, \dots, s_D) = \text{Re} \sum_{k_1, \dots, k_D} d_{k_1, \dots, k_D} \prod_{l=1}^D \text{Re} \left\{ \frac{z_l}{z_l - u_{lk_l}} - \frac{1}{2} \right\}$$

Of course the FT cannot construct an absorption-mode spectrum unless matched pairs of data sets are available (either N - and P - or sine and cosine) and in some cases this may save considerable instrument time, particularly with 3D or 4D spectra.

4.3 2D Spectral Estimation by RRT

As in the 1D case, the spectral estimation can be done directly by evaluating the resolvent matrix element in equation (24). For simplicity here we present only the 2D expression. Let $\tilde{\mathbf{R}}_l = \tilde{\mathbf{U}}_0 - \tilde{\mathbf{U}}_l/z_l$, ($l = 1, 2$). The 2D RRT spectral estimate then becomes

$$I(s_1, s_2) \approx \tilde{\mathbf{X}}_1^T \tilde{\mathbf{U}}_0 \tilde{\mathbf{X}}_2 - \tilde{\mathbf{C}}^T \frac{(\tilde{\mathbf{X}}_1 + \tilde{\mathbf{X}}_2)}{2} + \frac{c_{00}}{4} \quad (27)$$

with the two frequency-dependent vectors $\tilde{\mathbf{X}}_l = \tilde{\mathbf{X}}_l(s_l)$, ($l = 1, 2$), computed by solving the regularized Hermitian linear least squares problems,

$$(\tilde{\mathbf{R}}_l^\dagger \tilde{\mathbf{R}}_l + q^2) \tilde{\mathbf{X}}_l = \tilde{\mathbf{R}}_l^\dagger \tilde{\mathbf{C}} \quad (28)$$

Note that the total number of the linear systems (28) to be solved for each 2D frequency window is equal to $N_{s_1} + N_{s_2}$, where N_{s_1} and N_{s_2} are the numbers of the frequency grid points, s_1 and s_2 , to plot the spectrum in the window. In practice, RRT is very fast indeed.

When only the complex DFT spectrum (6) is of interest, RRT is, arguably, the most consistent approach. Once again, as in 1D case, using exact arithmetic for noiseless case when $N_{\text{total}} \geq 4K$ (i.e., for the well defined mD HIP), the estimate (27) is essentially exact. In practice, however, there are several factors that affect the convergence; the regularization parameter q being an adjusting knob to choose between the high-resolution regime ($q \sim 0$), and noisy spectrum, and the low resolution regime (large q) with strong suppression of the artifacts.

Even though various spectral representations can be produced by RRT, unfortunately, it is difficult to compute a double-absorption spectrum by the 2D RRT using only a single purely phase modulated data set. Because a direct line list is not produced in RRT its scope is more limited. Thus FDM with its potential ability to generate a direct line list seems much more appealing.

5 PRACTICAL CONSIDERATIONS

The foregoing mathematical development, while of interest to those with training in alternative methods to the FT, will not be transparent to a typical experimentalist primarily interested in the question ‘What’s in it for me?’. In the following, a more pictorial and qualitative exposition will be used.

The first thing to keep in mind is that FDM is most useful when the data is likely to fit the model of discrete Lorentzian lines (7), and when the time-frequency uncertainty principle is limiting the FT resolution substantially. Very noisy data does not fit the model, as noise cannot be encapsulated by any parametric description with a limited number of parameters. Lines in solids are usually not purely Lorentzian, which may limit the application of FDM. Likewise, data that has been sampled essentially well into the noise, cannot magically be processed to extract small splittings well within the instrumental linewidth. When using FDM the key question is this: If the data could be fully sampled in all dimensions, would the spectrum look like a discrete number of Lorentzians? If it would, then the same result can be obtained by FDM with much shorter data records. But if it would not, then FDM may not be useful. The presence of t_1 -noise, which is definitely non-Lorentzian, must also be kept in mind. Generally speaking, FDM is a method to use on high-quality spectra that have been recorded expertly, using the best available technology. It is not a method to clean up bad data sets.

FDM is particularly advantageous in so-called Constant Time (CT) experiments, in which a fixed time, denoted $2T$, is used for chemical shift encoding by changing the position of a 180° refocusing pulse. These experiments are often employed in the study of uniformly labeled proteins. The interferograms from CT-HSQC experiments show essentially no decay in the indirect dimension(s) and so are, by definition, transform limited. The full-width at half-maximum (FWHM) of the sinc-function, resulting from transformation of an unapodized CT signal, is $0.6034/T$. Apodization by a cosine function, $\cos(\pi t/2T)$, reduces sidelobe amplitude to less than 5% of

the main peak, but increases the FWHM to $0.8197/T$. Thus the transform-limited resolution is about 63 Hz, or 0.5 ppm at 125 MHz ^{13}C frequency, for a typical CT experiment with $2T = 26$ ms. For a hypothetical CT experiment with $2T = 4.7$ ms, lines no narrower than 348 Hz can be expected. To do better than this, some alternative to the FT must be used. Note that simply increasing $2T$ is not usually possible, as catastrophic loss of signal by transverse relaxation can ensue, especially for the important C_α resonances.

It might be tempting to assume that FDM, as it fits the lines including their widths, could give essentially infinite resolution in a CT-HSQC experiment: after all, the lines should have nearly zero width in F_1 . Very narrow lines can indeed be obtained, *but only if there are not too many of them, too closely spaced*. In other words, FDM cannot give infinite resolution, but only resolution commensurate with the local density of basis functions. This resolution is, as described above, dependent roughly on the *product* of acquisition times, so that some information in the acquisition dimension can be used to improve that in the shorter dimension, provided the signal does not decay too quickly.

The situation is shown in Figure 1, with closed shapes showing hypothetical peak positions, and crosses showing

Figure 1 A schematic representation of how FDM treats a local spectral region. At the top, peaks are represented with circles and Fourier basis functions with crosses. At the bottom is the expected result after diagonalization. The left-hand panels show a situation in which four basis functions are available to try to fit the seven genuine peaks. A ‘best effort’ fit leaves only one line converged, with the other three pairs fit as broader singlets. In the right-hand panels, eight basis functions are available because twice as much data has been sampled in the vertical dimension. Five of the seven peaks can be resolved, but the pair in the lower left-hand quadrant cannot, because they are degenerate in the vertical dimension. (Doubling the sampling in the horizontal dimension would, of course, resolve the two peaks)

the position of 2D Fourier basis functions. The top panels represent the initial matrix construction, and the lower panels are the FDM output. On the left panels, the local density of functions is four, but there are seven peaks present. Diagonalization does not change the size of the basis, so only four peaks can be used to fit seven. The result is shown in the lower panel, with three broad (and unstable) features masquerading as three sets of two lines, and one converged feature. In the right panel, the basis density is increased to eight by taking twice as many points in the vertical dimension. Now the vertical pair in the top right quadrant is resolved completely, as is the pair in the lower right quadrant, in which the F_1 frequencies are close, but not identical. However, the pair in the lower left quadrant is not resolved. The F_1 frequencies are nearly identical, so that increasing the sampling along F_1 does not help much: even though there are two basis functions in the vicinity, the two lines cannot be resolved. This kind of local convergence, in which more crowded spectral regions are the last to ‘settle down’, is completely different than the slow but uniform convergence familiar from FT analysis. This behavior can be rationalized within a linear algebraic context. If two lines have equal frequencies (and linewidths), e.g., along F_1 (or if both of these are very close in practical terms), then $\hat{U}_1$ will have two degenerate eigenvalues. In order to resolve these two peaks in the F_2 dimension, one needs a basis of at least two linearly-independent vectors containing the corresponding two-dimensional eigensubspace of $\hat{U}_1$. However, those cannot be constructed using, for example, Krylov vectors $\Phi_{n_1, n_2} = \hat{U}_1^{n_1} \hat{U}_2^{n_2} \Phi$ with some fixed values of n_2 and any number of different n_1 values. One needs at least two vectors Φ_{n_1, n_2} with different n_2 . In practice, these considerations must be applied locally in the frequency domain, i.e., using the Fourier basis (the crosses), rather than Krylov basis, and have less obvious consequences because of several other factors. For instance, what happens to the ‘unused’ basis functions? They end up fitting residual noise or non-Lorentzian components in the skirts of the peaks. How far can an initial basis function ‘move’? That depends on the SNR. The higher it is, the more freedom the crosses acquire to ‘lock on’ to a signal peak. It is thus important to emphasize that the ideal kind of spectrum for FDM analysis is one in which the features are a fixed number of randomly distributed sharp Lorentzians that are well above the noise floor. This kind of signal can always be dominated by the available basis functions as more data is acquired. High noise levels effectively rob the algorithm of basis functions by pinning down many of them to fit noise locally. Spectra like COSY, in which many lines are absolutely degenerate, and there are locally dense regions within cross peak multiplets, cannot benefit much, if at all, from FDM. That is, it will still require many increments to resolve a COSY spectrum properly and, as new weak cross peaks continuously emerge when the evolution time is incremented, convergence may never be achieved at all.

6 SELECTED APPLICATIONS

6.1 2D Constant-Time HSQC Spectra

With these cautions in mind, the results for protein NMR can be startlingly good. The three figures (Figures 2–4), show

Figure 2 A small portion of the CT-HSQC spectrum of human ubiquitin (1 mM solution, 500 MHz proton frequency) obtained with a very short CT period of 4.7 ms and processed by 2DFT. The C_{α} - H_{α} region is displayed. The broadening in the vertical dimension is primarily due to the time-frequency uncertainty principle, so that, while sensitivity is quite good, resolution is sufficient to make only a small fraction of the assignments

the C_{α} - H_{α} region of a CT-HSQC spectrum of uniformly labeled human ubiquitin (1 mM, 5 mm tube, 500 MHz) using a very short 4.7 ms CT. The FT spectrum shows the expected broad peaks in F_1 , in accordance with the time-frequency uncertainty principle. Using Mirror-Image Linear Prediction in F_1 ¹⁸ and FT in F_2 improves matters somewhat, but the spectrum is a distant second to the FDM2K result, in which nearly every resonance is fully resolved except for the predictable non-convergence of the most congested region. The peaks are genuine, as can be verified by acquiring a much longer CT data set.¹⁸

6.2 45° Projections of 2D J Spectra

The unique ability to create a pseudo-absorption spectrum from a single phase-twist FT spectrum is quite useful when there is only a single data set, as in 2D J -spectroscopy.^{5,9,10} In this case, the improved resolution can be used to construct a proton-decoupled proton spectrum by computing the phase-sensitive 45° projection. This projection vanishes in the FT spectrum because of the phase-twist line shape. Furthermore, this decoupling can be applied to other mD spectra, to condense proton multiplets into sharp singlets, thereby improving the resolution substantially. This combination of spectroscopic simplification with alternative methods of analysis is opening up new possibilities for future research. An example of a 1D

Figure 3 The same data set as in the two previous figures, using mirror-image Linear Prediction in the vertical dimension to first extend the data length by a factor of two, followed by FT processing. Resolution is better than the 2DFT, but not as good as 2D FDM, as can be clearly seen by examining the clusters of peaks in the lower part of the figures

45° projection of a 2D J data set, with only a few increments in the J dimension, is shown in Figure 5. The results are quite encouraging, although more work needs to be done to make the method a turn-key experiment. Proper regularization of these projections is an area of current research.

7 REMAINING PROBLEMS

Both 1D FDM and RRT (its offspring) are essentially developed and well tested techniques that are generally as reliable as the FFT, sufficiently fast, and can often deliver resolution beyond the FT uncertainty relation if the data can be well represented by Lorentzians and is not very noisy.

FDM provides one with an effective evolution operator $\hat{U}$ with eigenvalues and eigenvectors directly related to the spectral parameters. However, the difficulties associated with the construction of a meaningful line list for data of poor quality (i.e., not characterized by equation (3)) exist. These difficulties are not associated with the lack of a reliable algorithm for selecting the ‘genuine’ poles and throwing away the ‘noise’ poles from the full list of complex eigenvalues of $\hat{U}$, but are rather conceptual, and caused by the intrinsic ambiguity of the line list for a general data set that, a priori, does not fit any particular parametric form.

The mD case is considerably more difficult. For example, the multidimensional spectrum cannot generally be constructed

Figure 4 The same data set as in the previous figure, but processed by FDM2K. No FT was used to construct the spectrum: it came directly from the FDM2K line list. To improve the appearance of the spectrum (cosmetically) Gaussian line shapes have been substituted for the Lorentzian lines that are the natural form of the FDM spectrum. Resolution is dramatically enhanced. The spectrum is completely converged except for the most crowded region, which shows the kind of non-convergence described when more local features are present than the number of local Fourier basis functions available to FDM

from the multidimensional line list, as the latter can be very hard to obtain. Fortunately, various spectra can be obtained by avoiding the line list construction and using the resolvent expressions. The resolvent operator formalism appears to be very convenient as it allows one to construct various types of spectra, including absorption-mode spectra (non-trivial spectral projections discussed above). The main computational problem associated with the implementation of the resolvent formulas is that one typically deals with very ill-conditioned matrices, causing the spectrum to be very unstable with respect to both the FDM parameters, and small variations of the input data. Thus, unlike the 1D case, there are major problems to be solved in the multidimensional versions of both FDM and RRT. For instance, for a typical 2D NMR data set, even with relatively high SNR, one has difficulties in constructing two adequate commuting effective evolution operators $\hat{U}_1$ and $\hat{U}_2$ describing the 2D signal. This, in turn, makes it difficult to construct an adequate 2D line list corresponding to equation (7). We believe that this problem is, as in the 1D case, a consequence of the ill-defined nature of equation (7), although the additional requirement that the operators $\hat{U}_i$ commute with each other makes the problem much worse than in 1D. Clearly, the key issue in mD FDM is to find a general computationally inexpensive

Figure 5 An example of direct calculation of a 1D 45° projection (the lowest trace) and multiplet cross sections by FDM. The upper trace corresponds to a conventional ^1H spectrum. The spectra were obtained using a purely phase modulated 2D- J signal of ditryptophan tripeptide⁹ with just $N_1 = 4$ points along the J -dimension. $N_{\text{FDM}} = 20$ calculations, with different number of points along the running time dimension in the range $N_2 = 11\,000$ – $12\,000$, were added together to obtain artifact free spectra. Only a small part of the spectrum is shown, while the two spectral widths were $SW_1 = 80$ Hz and $SW_2 = 8$ kHz

and robust procedure that could be applied to regularize the FDM equations. At the present stage the problem is only partially solved. For example, the regularization procedure in RRT is very efficient, but, unfortunately, it can be used only as a spectral estimator and cannot easily overcome some of the DFT limitations. Regularization of RRT is not directly extendable to FDM, although several methods have already been developed, such as truncated SVD of U_0 or FDM averaging.^{10,12,16} Unfortunately, the former is not generic, while the latter is computationally very expensive and cannot be used to construct a multidimensional line list. Currently, the most promising regularization technique seems to be that associated with FDM2K.¹⁵ Its implementation is computationally very simple and inexpensive, although, at this stage, it is not clear how general and reliable it is for various types of NMR data.

To conclude, the main avenues for the future research seem to be the following.

- (i) Given the matrix representations of the evolution operators, $\hat{U}_1$, $\hat{U}_2$, etc., in a non-orthonormal basis, which are possibly very ill-conditioned, find a fast and reliable method of evaluating various resolvents associated with these operators.

- (ii) Given the matrix representations of the evolution operators, construct a set of commuting effective Hamiltonians $\hat{\Omega}_1$, $\hat{\Omega}_2$, etc., with eigenvalues and eigenvectors yielding the line list.

Both goals are associated with finding reliable and computationally inexpensive regularization techniques.

1 INTRODUCTION

The INADEQUATE (Incredible Natural Abundance Double QUAntum Transfer Experiment) consists of a special pulse sequence which eliminates the NMR signals from isolated spins (spin system A) displaying signals from coupled spins (spin system AX or higher spin systems). It is of great importance when applied to molecules with skeleton elements such as carbon, silicon or tungsten, all of which contain a small percentage of spin- $\frac{1}{2}$ isotopes embedded in magnetically inactive isotopes. The large signals from the spin type A are eliminated, while the tiny signals from the rarely occurring spin types AX are well displayed. Analysis of the AX type spectra gives not only the coupling J_{AX} but also the connectivity pattern of the skeleton atoms in molecules of unknown structure. Most important is the structural determination of carbon compounds including those that cannot be analyzed by X-ray, either because the compound does not crystallize or because the crystals obtained exhibit unfavorable properties. Representative examples for the determination of connectivities by INADEQUATE are the carbon compound (1) and the silicon compound (2).

In principle, the determination of the connectivity pattern via AX coupling can also be performed by conventional NMR spectroscopy; this will be demonstrated in Section 2. However, a severe drawback is the large A type signals; therefore, one- and especially two-dimensional INADEQUATE spectra are preferred (Sections 3 and 4). Due to the low abundance of neighbored AX spins efforts to improve the sensitivity of INADEQUATES have received much interest (section 5).

Section 6 describes the application to various elements. As carbon compounds are the main objective of the INADEQUATE experiment, the principles of tracing atomic connectivities by conventional NMR or INADEQUATES will be explained with the aid of the element carbon (for a review see Buddrus and Bauer¹).

2 CONVENTIONAL ^{13}C NMR SPECTROSCOPY

The element carbon contains 98.9% of the isotope ^{12}C (spin quantum number $I = 0$) and 1.1% of the isotope ^{13}C ($I = \frac{1}{2}$). Almost all carbon compounds thus consist of a number of isotopomers. Thus for example even the simple three-carbon molecule 1-iodopropane exists as a mixture of the following eight isotopomers (when hydrogen is considered to be isotopically pure):

$\text{H}_3\text{C}-\text{CH}_2-\text{CH}_2-\text{I}$		
96.73%		
$\text{H}_3^{13}\text{C}-\text{CH}_2-\text{CH}_2-\text{I}$	$\text{H}_3\text{C}-^{13}\text{CH}_2-\text{CH}_2-\text{I}$	$\text{H}_3\text{C}-\text{CH}_2-^{13}\text{CH}_2-\text{I}$
1.08%	1.08%	1.08%
$\text{H}_3^{13}\text{C}-^{13}\text{CH}_2-\text{CH}_2-\text{I}$	$\text{H}_3^{13}\text{C}-\text{CH}_2-^{13}\text{CH}_2-\text{I}$	$\text{H}_3\text{C}-^{13}\text{CH}_2-^{13}\text{CH}_2-\text{I}$
0.01%	0.01%	0.01%
$\text{H}_3^{13}\text{C}-^{13}\text{CH}_2-^{13}\text{CH}_2-\text{I}$		
0.0001%		

The proportion of an isotopomer with a ^{13}C atom in a certain position is $0.011^1 \times 0.989^{n-1}$ (n is the number of carbon atoms in the molecule), that of an isotopomer with two ^{13}C atoms in defined positions (whether these are directly neighboring or not) is $0.011^2 \times 0.989^{n-2}$, and so on. This means that only one single molecule in 10 000 has two neighboring ^{13}C atoms in a certain position.

Broadband decoupling of the attached protons converts isotopomers with only a single ^{13}C nucleus to spin systems of type A, so that singlet signals are observed (this is the conventional ^{13}C NMR spectrum). Isotopomers with two ^{13}C nuclei behave just like those with only a single ^{13}C nucleus if the ^{13}C nuclei are separated by several bonds. If however the ^{13}C nuclei are separated by only a few bonds (generally one to three) they couple and, thus, unless they are isochronous, they form AB or AX spin systems whose spectra consist of two doublets. $^1J(\text{C},\text{C}')$, the coupling constant over one bond, depends on the hybridization of the carbon orbitals and on the substituent X in the fragment $^{13}\text{C}-^{13}\text{C}-\text{X}$ and varies between about 35 and 75 Hz. Coupling constants over two or three bonds are much smaller, typically between 0 and 5 Hz.

In ^{13}C NMR spectra with a sufficient signal-to-noise ratio (>500:1) the weak signals of the coupled nuclei can be seen on both sides of the strong singlet signals of the isolated ^{13}C nuclei (see Figure 1). The intensity ratio of the singlet to one of the four signals of the coupled nuclei is about 200:1. If the various coupling constants have different values, a comparison of the coupling constants of all ^{13}C nuclei in a molecule shows which atom is bonded to which, yielding the exact structure of the carbon skeleton. Thus the C-2 signal of (3) (Figure 2) is accompanied by two pairs of satellite signals, the splitting of which proves the structure of this part of the molecule.

The extraction of all 1J values from a conventional ^{13}C spectrum is difficult, because spinning sidebands or signals due to impurities can be incorrectly identified as satellite signals

Figure 1 Term scheme and NMR spectrum of a ^{13}C – ^{13}C fragment. (a) Term scheme: 1, 2, 3, and 4 are allowed single quantum transitions, and 5 and 6 forbidden zero- and double-quantum transitions respectively. (b) and (c) NMR spectra of an AB and an AX spin system. The chemical shifts of the coupled ^{13}C nuclei are shifted to lower frequency by between 0 and 0.03 ppm (isotope effect on the chemical shift). (Reproduced by permission, from Buddrus and Bauer¹)

or satellite signals can be hidden (by other satellite signals or by signals due to isolated ^{13}C nuclei).

Many of these difficulties can be avoided when instead of the conventional recording technique the pulse sequence INADEQUATE is used; this sequence was first suggested by Bax et al.² The basis for this particular pulse sequence is the method of multiquantum NMR spectroscopy developed by Aue and Wokaun et al.^{3,4} (for reviews see Bodenhausen and Braunschweiler et al.^{5,6}).

The influence of high frequency pulses on coupled spin systems is described by the density matrix formalism, or in a less cumbersome way by the product operator formalism (see Sørensen et al.⁷). For application of the density matrix formalism to the INADEQUATE experiment see the review by Buddrus and Bauer¹ and Bax.⁸ Where necessary, the results of this treatment will be presented here either in a descriptive way or as drawings of vector models.

3 ONE-DIMENSIONAL INADEQUATE ^{13}C NMR SPECTROSCOPY

The INADEQUATE method consists of a pulse sequence which in the simplest version is executed twice (the ‘two-step cycle’), whereby the phase of the last 90° pulse and of the detector data acquisition system differ in the two steps. Two FIDs are thus obtained, and the coaddition of these leads to the elimination of the strong signals due to the isolated ^{13}C nuclei.

Step 1: $90^\circ_x - \tau - 180^\circ_y - \tau - 90^\circ_x - \Delta - 90^\circ_x$ – data acquisition (x)

Step 2: $90^\circ_x - \tau - 180^\circ_y - \tau - 90^\circ_x - \Delta - 90^\circ_y$ – data acquisition ($-y$)

The effect on a C_2 fragment is shown in Figure 3. The first part of the INADEQUATE pulse sequence ($90^\circ_x - \tau - 180^\circ_y - \tau$) is identical to a homonuclear spin echo experiment. It produces transverse magnetization from the isolated spins A in the y direction and from the coupled AX spins in $\pm x$ direction

Figure 2 25 MHz $^{13}\text{C}\{^1\text{H}\}$ NMR spectrum of (3) (0.5 g) + $\text{Cr}(\text{acac})_3$ (acac = acetylacetonate) (about 10 mg) (for T_1 relaxation enhancement) in CDCl_3 (1.5 mL). Digital resolution: 0.5 Hz per data point. (a) Single transient. (b) 60 000 transients, repetition interval 4 s (partial spectrum). $J(2,3) = 72.9 \text{ Hz}$, $J(2,9) = 57.7 \text{ Hz}$. (Reproduced from Buddrus and Bauer¹)

(antiphase magnetization). The subsequent 90°_x pulse shifts the magnetization of the isolated spins to the $-z$ direction, while the antiphase magnetization from the AX spins is transferred into the so-called double quantum coherence, directed along the y axis of the rotating double quantum coordinate system. The double quantum coherence does not represent observable magnetization. The last 90° pulse (the ‘read pulse’) comes from the x direction (first step) or from the y direction (second step); it shifts the magnetizations from the isolated spins into the $-y$ and x direction respectively, and the double quantum coherence is converted to single quantum coherence directed along the x' or y' axis respectively. The phase of the detector is then switched in such a way that it follows only magnetizations of the AX spin system. Addition of the two FIDs leads to the addition of magnetization of the AX spins, *but elimination of the large magnetization from the isolated spins*. Finally, Fourier transformation affords the frequency spectrum, which only contains the two doublets (in antiphase to each case) of the AX spin system.

A one-dimensional INADEQUATE ^{13}C NMR spectrum consists in theory only of signals from coupled nuclei: the unwanted signals due to isolated ^{13}C nuclei (whether from the main component or from impurities) as well as the spinning sidebands from these signals are not present. The power of the one-dimensional INADEQUATE method is demonstrated in Figure 4. Due to the presence of five oxygen atoms distributed

Figure 3 The INADEQUATE pulse sequence and its effect on a C_2 fragment. M_1 , M_2 and m_1 to m_4 are the magnetizations of the isotopomeric fragments $^{13}C-^{12}C$, $^{12}C-^{13}C$ and $^{13}C-^{13}C$. The delay time τ and the switching time Δ (about $10\mu s$) are not shown to scale. M_1 , $m_1(+)$, $m_2(-)$: the Larmor frequency of m_1 is larger and that of m_2 smaller than that of M_1 (this is the situation after the first 90° pulse). For clarity the fates of M_2 , m_3 and m_4 have been considered only after FT. (Reproduced from Buddrus and Bauer¹)

over compound (4) the couplings $^1J(C,C)$ differ sufficiently so that all connectivities can be unequivocally traced (e.g. between C-1 and C-6a) establishing the proposed structure and excluding alternative structures.

As can be seen from Figure 4, the intensities of the satellite signals differ from one AX spin system to another; for instance, the intensity ratio at the C-4 signal is about 1:0.5:0.5. This results from different $^1J(C,C)$ values. If the actual coupling constant (J_a) differs from the value J used in $\tau = 1/[4 \times ^1J(C,C)]$, the intensity I will be decreased in the AX case according to equation (1), since the magnetization is no longer directed exactly along the $\pm x$ axis (Figure 3).

$$I = I_{\max} \sin(2\pi J_a \tau) \quad (1)$$

However, the results of this deviation from ideality are not serious: 50% or more of the maximum intensity $I_{\max}$ is still observed when $\frac{1}{3}J \leq J_a \leq \frac{5}{3}J$.

4 TWO-DIMENSIONAL INADEQUATE ^{13}C NMR SPECTROSCOPY

If the ^{13}C , ^{13}C coupling constants differ only slightly from one another then an overlap of satellite signals (for AX spectra) or ambiguities in recognizing the coupling partner may occur. Difficulties of this type can be avoided when the INADEQUATE sequence is made two-dimensional. The pulse sequence for the two-dimensional experiment is almost

exactly the same as that in one dimension: the change is that the short switching time Δ in Figure 3 is replaced by the time t_1 , which is incremented stepwise. When $t_1 = 0$, the nonobservable double quantum coherence is directed along the y' axis of the double quantum coordinate system [Figure 5(a)]. It then rotates at the double quantum frequency ν_{DQ} in the x,y plane of this coordinate system; after the evolution times $t_1 = n/(4\nu_{DQ})$, ($n = 1-4$), it is directed as shown in Figure 5. Conversion to single quantum coherence by means of the 90° read pulse, followed by Fourier transformation, gives the satellite signals, the intensity of which is now modulated by ν_{DQ} .

$$\nu_{DQ} = \nu_A + \nu_X - 2\nu_0 \quad (2)$$

ν_A , ν_X : resonance frequency of the nuclei A or X; ν_0 : exciting frequency.

A second Fourier transformation, in this case applied to the intensity variation of the satellite signals, gives the double quantum frequency ν_{DQ} of the AX spin system. Since this frequency is equal for all four signals of an AX spin system, the satellite signals appear in the same row ($f_1 = \text{constant}$) of the two-dimensional spectrum, though with differing phase. The situation is analogous for each further AX spin system. The advantage over a one-dimensional spectrum is that no overlap can occur, even when $^1J(C,C)$ values are equal, since the double doublets of each of the different AX spin systems occur in different rows.

Figure 6 shows the two-dimensional INADEQUATE spectrum of the initially unknown compound (5). In order to

Figure 4 25 MHz $^{13}\text{C}\{^1\text{H}\}$ NMR spectrum of (4) (1.2 g) + $\text{Cr}(\text{acac})_3$ (20 mg) in CDCl_3 (1.0 mL). (a) Conventional spectrum: 1000 transients. (b) One-dimensional INADEQUATE spectrum; $\tau = 1/(4J)$ ($J = 50$ Hz); 122 000 transients; repetition interval 4 s (total measuring time 135 h); digital resolution 0.5 Hz per data point. (c) Expanded INADEQUATE spectrum. *Solvent signal. (Reproduced from Buddrus and Bauer¹)

identify the carbon skeleton, the signals are numbered from left to right, the corresponding numbers are joined up as in (5a), and finally the numbers are replaced by the corresponding CH_n fragments, which have previously been obtained from a DEPT experiment. The result is (5b); after the keto group ($\delta = 229.5$ ppm) has been added, the final structure (5c) [(5) in Figure 6] is obtained.

If all the contours in a two-dimensional (2D) INADEQUATE spectrum are visible, its interpretation requires little time and can be carried out without any particular spectroscopic or chemical experience.

4.1 Phase Cycling

In practice, the two-step cycle described above affords only an incomplete elimination of the signals of isolated ^{13}C nuclei. The reasons for this are firstly the nonideal spectrometer conditions such as pulse angle errors and phase errors, and

secondly differences between the two recording channels (receiver systems), each of which has its own analog–digital converter and amplifier. However, the residual signals can be reduced further by using extended phase cycles. The double quantum coherence produced by the pulse sequence $90^\circ_x - \tau - 180^\circ_y - \tau - 90^\circ_x$ can be read by a 90°_{-x} or 90°_{-y} pulse as well as by a 90°_x or 90°_y pulse. This 4-step cycle² compensates for the inequality of the recording channels. Additional cycling through the phases of the other pulses results in a 2^n step cycle ($n = 2, 3 \dots 8$) ending up with 256 steps (for details see the review by Buddrus and Bauer¹).

4.2 Quadrature Detection

As shown by Figure 5 the 90° read pulse in the two-dimensional version results in an amplitude modulation: the Fourier transformation of the FIDs gives not only the required signals (echoes) with double quantum frequency ν_{DQ} , but also the unrequired reflected signals (antiechoes) whose frequency is $\nu_{-\text{DQ}}$ [marked in Figure 5(e) by crosses]. The unrequired signals can be eliminated by quadrature detection, which is achieved by executing two measurements at each setting of t_1 . The crucial step is to induce a 90° phase shift of the double quantum coherence. This can be achieved either by altering the phase of the first three pulses of the sequence by 45° or by rotating the double quantum coherence itself by a so-called

Figure 5 Influence of the evolution time t_1 (which replaces Δ in Figure 3) on the magnetization of a C_2 fragment. For clarity only the effect of the read pulse 90°_x (step 1 in Section 3) on the magnetizations m_1 to m_4 is shown and the notations m_3 and m_4 are omitted. One should note the general agreement between (a), (b) and (c) and Figure 3. (e) The contours (full and broken circles; above and below the plane of the paper respectively) of the four signals m_1 to m_4 of an AX spin system. The midpoints of those contours which belong together lie on the frequency diagonal $f_1 = 2f_2$ (f_1, f_2 : double and single quantum frequencies respectively). The positions marked by crosses are those of the antiechoes observed in experiments without quadrature detection in f_1 . (Reproduced from Buddrus and Bauer¹)

45°_z pulse, which is in practice replaced by the combination $90^\circ_{-x} - 45^\circ_{-y} - 90^\circ_x$.

$$90_x^\circ - \tau - 180^\circ - \tau - 90_x^\circ - 45_z^\circ - t_1 - 90_x^\circ - \text{acquisition}$$

For further discussion and experimental details see Bax et al.⁹ and Lambert et al.¹⁰ The spectrum in Figure 6 has been obtained after quadrature detection in both dimensions.

5 SENSITIVITY OF THE INADEQUATE

The poor sensitivity of the INADEQUATE method has already been mentioned. In the case of carbon compounds 1–2 days are needed (with 0.5–1 mmol of the substance and a 9.4 T spectrometer) to get a spectrum with a sufficient signal-to-noise ratio (S/N). An increase in the sensitivity can be achieved by transfer of polarization from protons to the insensitive nuclei: INEPT–INADEQUATE and

Figure 6 100 MHz $^{13}\text{C}\{^1\text{H}\}$ NMR spectrum (aliphatic part) of (5) (1.2 g) + $\text{Cr}(\text{acac})_3$ (10 mg) in CDCl_3 (1.5 mL). (a) Conventional spectrum. (b) Two-dimensional INADEQUATE spectrum, $\tau = 1/(4J)$ ($J = 35$ Hz), quadrature detection in both dimensions. $f_2 = 8771$ Hz (8K data points), $f_1 = 8771$ Hz per 512 data points. 113 rows were recorded, each with 128 transients; repetition interval 4 s; measuring time 16 h. The data matrix was zero filled to $16\text{K} \times 512$ and Fourier transformed after Gaussian multiplication in f_1 and f_2 . (Reproduced from Buddrus and Bauer¹)

DEPT–INADEQUATE. The factor of increase is small for ^{13}C ($\geq \frac{4}{3}$) and larger for ^{29}Si ($\geq \frac{5}{1.5}$); in addition the repetition interval can be decreased as long as the relaxation times T_1 of the protons are shorter than those of the insensitive nuclei ^{13}C , ^{29}Si , etc. A remarkable increase in sensitivity has been obtained by the ^1H -detected method INSIPID. The interfering signals from protons attached to ^{12}C were eliminated by field gradient pulses. See Weigelt and Otting.¹¹

Due to the logic of a 2D INADEQUATE spectrum, analysis is also possible with the aid of a computer program. Contrary to manual interpretation even tiny satellite signals may be recognized and interpreted. Mutual addition of the four signals of an AX spin system of a phase sensitive 2D INADEQUATE spectrum can also be carried out by a computer. This gives a S/N improvement of two, equivalent to a reduction of measurement time by a factor of four. Figure 7 demonstrates

this improvement for the weakest satellite signals (signals from the adjacent quaternary carbons) of compound (6).

6 APPLICATIONS: ORGANIC AND INORGANIC COMPOUNDS

6.1 Organic Compounds

6.1.1 Constitution

Most convincingly ^{13}C , ^{13}C spin–spin coupling can be used for the determination of the constitution of the following types of carbon compound, the structures of which can either not be determined or determined only with difficulty using other NMR methods (including 2D techniques):

1. Hydrocarbons or hydrocarbon-like compounds (1, 7, 8): their ^1H NMR spectra are complex, while normal ^{13}C NMR spectra do not afford much information.

2. Compounds in which those carbon atoms which are important for determining their constitution carry few if any hydrogens. In such cases ^1H NMR is unsuccessful because of the lack of hydrogen atoms, while normal ^{13}C spectra can often not be interpreted with certainty. Examples are highly chlorinated compounds (9), (10) or certain cycloaddition products (11), (12); the wavy lines in the formulas of the latter indicate the starting materials used and make clear the regiochemical problems, which can easily be solved by INADEQUATE.

3. Compounds with particular symmetry properties, independent of whether the carbon atoms are hydrogen-rich or hydrogen-poor. Thus, the isomers (13) and (14) (head-to-head and head-to-tail products from photodimerizations) can be distinguished simply from the ratio of the satellite pairs at the CH signals: 1:1 for the former and 1:2 for the latter.¹

Figure 7 Cross peaks of the row $\nu_{DQ} = \nu_{C-1} + \nu_{C-5} - 2\nu_0$ from the 2D INADEQUATE spectrum of (6). (a,b) Untreated. (c,d) Filled with zeros at positions where no double quantum signal can occur. (e,f) Treated with mutual addition of the four satellite signals. Note the S/N improvement in (f) compared with (b). (Reproduced from Lambert and Buddrus¹²)

6.1.2 Assignment

The INADEQUATE method can also be applied simply to assign ^{13}C NMR signals of known compounds. The results are unequivocal, contrary to those obtained from the incremental method or from comparison with model compounds. Numerous examples for carbon (and also silicon) compounds are described in the literature.

6.1.3 Biosynthetic Studies

Carbon-13 labeled precursors have long been used in the determination of biosynthetic pathways. One important precursor is labeled sodium acetate yielding labeled polyketides. Most useful is the incorporation of two adjacent ^{13}C nuclei which give information on folding, rearrangement, etc. of polyketide chains. For a review see Floss and Beale,¹³ see also Buddrus and Bauer.¹ Double labeling is achieved by adding either a 1:1 mixture of 1- and 2- ^{13}C acetate or an approximately 3:1 mixture of nonlabeled and doubly labeled acetate. An isotopomeric mixture of polyketides results in the ^{13}C

nuclei neighboring at C-2 and C-3 [Figure 8(g)] or neighboring at C-1 and C-2 or at C-3 and C-4 [Figure 8(l)]. As a result of this labeling, ^{13}C , ^{13}C satellite signals of increased intensity are observed. The increase of the satellite signals is remarkable. A 3:1 mixture (see above) gives a theoretical increase of about 2500 if no dilution by additional unlabeled acetate occurs. Therefore, amounts between 100 μg and a few mg of the polyketide are sufficient, even for molecules containing about 50 carbon atoms.

6.2 Inorganic Compounds

The INADEQUATE pulse sequence can also be used to investigate inorganic compounds containing elements with a spin- $\frac{1}{2}$ isotope of low natural abundance (<15%): examples are provided by the elements silicon (4.7% ^{29}Si), tin (7.6% ^{117}Sn , 8.6% ^{119}Sn) and tungsten (14.3% ^{183}W). The INADEQUATE spectra contain only signals from the AX spin system, from which the atomic skeleton of the molecule can be derived; beyond this, determination of the 1J values and assignment of the NMR signals of A type nuclei is possible.

Most important is the application to silicon compounds, either as liquids or as solids. The two ^{29}Si isotopes are either directly connected (as in silanes) or separated by one oxygen atom (as in siloxanes or silicates). Therefore, the delay time τ in the INADEQUATE pulse sequence has to be adjusted to either $1/(4\ ^1J)$ or $1/(4\ ^2J)$. The values in silicon compounds

Figure 8 Distribution of ^{13}C nuclei in polyketide chains: sections of chain after incorporation of differently labeled acetates. For explanation see text. ^{12}C is denoted by $\circ$ or $\square$, ^{13}C by $\bullet$ or $\blacksquare$. Isotopomers which contain neighboring ^{13}C nuclei at increased abundance are also indicated by bold lines at the appropriate positions; compare (g), (i) and (l). (Reproduced from Buddrus and Bauer¹)

are comparable to those in carbon compounds.

Figure 9 shows the 2D ^{29}Si -INEPT-INADEQUATE spectrum of the cyclosilane (15). The ^{29}Si - ^{29}Si connectivities prove that the structure is that of (15) while structure (16) with adjacent trimethylsilyl groups can be excluded. Due to large 2J coupling, not only connectivities through one bond are observed (horizontal lines in the spectrum) but also those through more than one bond (a-c; e-f). However, long-range coupling is easily recognized by its value, and so there is no ambiguity in establishing the structure.

Compounds in the solid state can also be investigated by 2D techniques such as COSY or INADEQUATE, provided

the MAS technique is applied; see Benn et al.¹⁵ MAS eliminates shielding anisotropies and direct dipole-dipole coupling, leaving indirect coupling through one or more bonds (J coupling). The linewidth can be as low as 1–20 Hz (under proton decoupling conditions where necessary). With 2D MAS-INADEQUATE several zeolites have been studied. Figure 10 shows the ^{29}Si MAS and MAS-INADEQUATE spectrum of (17), a zeolite with seven crystallographically inequivalent tetrahedral lattice sites indicated by Si1, Si2 ... Si7.

Starting from a signal with a well known assignment all other signals can be unequivocally assigned. Generally, INADEQUATE is superior to COSY, because in the latter method diagonal signals can interfere with cross peaks (compare T_4T_6).

Other nuclei, which have been investigated by INADEQUATE, either in liquids or solids, are: ^{183}W , ^{119}Sn and ^6Li . Interestingly, the 2D INADEQUATE experiment can also be applied to compounds with elements consisting mainly or entirely of only spin- $\frac{1}{2}$ isotopes (H, P or F). Such compounds are e.g. hydrogen containing organic compounds yielding multispin systems. The behavior of multispin systems (ABC; ABCD ...) toward the INADEQUATE pulse sequence is treated by Braunschweiler et al.¹⁷ In the case of the simple three-spin system AMX a total of six double quantum coherences is possible. Several proton spin systems have been studied by INADEQUATE. The advantages and disadvantages with respect to COSY are discussed by Boyd et al.¹⁸

7 OUTLOOK

Two-dimensional INADEQUATE spectroscopy is a useful method for the determination of the constitution of unknown carbon and silicon and other compounds. The simplicity and logic of the spectra are fascinating. There is no ambiguity. The inherent insensitivity has been reduced to some extent in the past and will surely be further reduced. The day will come when a few mg of an unknown compound from a plant or a microorganism, measured overnight, will yield the secret of its constitution by daybreak.

1 INTRODUCTION

INEPT (insensitive nuclei enhanced by polarization transfer) is a pulse sequence used to transfer spin-state polarization from one nucleus to another. Its original use was to transfer polarization from protons to nuclei X of lower magnetogyric ratio γ , in order to enhance the signals of X: it has also been widely used to determine the multiplicities of X signals (i.e. how many protons are directly bonded to a given X). Although now partly superseded by the DEPT sequence, it is still in widespread use, and is frequently incorporated as a building block into more complex pulse sequences. The main significance of INEPT in the development of multiple pulse NMR methods was that it was one of the first sequences to use a modulated spin echo to effect a broadband (i.e. independent of chemical shift) manipulation of the spin system, a feature of many subsequent experiments. Several useful reviews have been published.^{1–4}

There are two main reasons for transferring polarization between heteronuclei: to transfer information (e.g. to establish scalar coupling relationships), and to enhance signal intensity. The latter benefit arises from the dependence of the intensity of an NMR signal on (inter alia) the spin state population difference (or polarization) across the transition concerned. In the high-temperature approximation, the Boltzmann equilibrium polarization is proportional to γ . Since protons are chemically ubiquitous and enjoy a high γ and a high natural abundance, polarization transfer is usually effected from protons to X, resulting in X signals that are a factor γ_H/γ_X stronger than those obtained from equilibrium X polarization. In the discussion that follows, the starting nucleus will be assumed to be the proton, although a variety of other nuclei have been used, including ^{31}P and ^{29}D .

In its basic form,⁵ the INEPT sequence consists of five pulses, and transfers polarization from protons to X (often ^{13}C) through one-bond couplings $^1J(\text{X}, \text{H})$:

$$\begin{array}{ccccccc}
 {}^1\text{H} & 90^\circ & & 180^\circ & & 90^\circ & \\
 & & \tau & & \tau & & \\
 \text{X} & & & 180^\circ & & 90^\circ & \text{Acquire}
 \end{array}$$

where all pulses have x phase unless otherwise indicated. The delay 2τ generates a spin echo modulated by the heteronuclear coupling; if $\tau = 1/[4^1J(\text{X}, \text{H})]$, the proton and X 90° pulses transfer the resultant antiphase proton magnetization to X. This

Table 1 Phase Cycling for the Refocused INEPT Sequence; Phase Shifts are Indicated as Multiples of 90° . For the Basic Sequence, ϕ_3 Follows the Cycle 0321 Throughout

ϕ_1	0202 0202 2020 2020
ϕ_2	0202 2020 1313 3131
ϕ_3	0321 2103 0321 2103
ϕ_4	0101 1212 0101 1212
Receiver	0123 0123 0123 0123

gives an X spectrum in which the multiplets are in antiphase with respect to the coupling $^1J(\text{X}, \text{H})$; no proton decoupling is used, since collapsing the antiphase multiplets would destroy the enhanced signal. Where $\text{X} = ^{13}\text{C}$, the comparative uniformity of one-bond $^1\text{H}-^{13}\text{C}$ couplings $^1J(\text{C}, \text{H})$ allows a single value of τ to be used for most types of carbon. Common chemical environments for CH_n groups give $^1J(\text{C}, \text{H})$ values in the range 120–170 Hz; a compromise value $\tau \approx 1.8$ ms generally gives good results. With longer delays it is possible to transfer polarization through long-range couplings $^nJ(\text{X}, \text{H})$, although the presence of multiple competing couplings can make this inefficient.

If a decoupled X spectrum is required, the antiphase X magnetization may be left to evolve for a time 2Δ into in-phase signal before decoupling is applied;⁶ to avoid large frequency-dependent phase errors in the X spectrum, refocusing is generally used. This gives the seven-pulse ‘refocused INEPT’ sequence⁷ (phase cycling is given in Table 1):

$$\begin{array}{ccccccc}
 {}^1\text{H} & 90^\circ_{\phi_1} & & 180^\circ_{\phi_2} & & 90^\circ_{\phi_3} & & 180^\circ_{\phi_4} & & \text{Decouple} \\
 & & \tau & & \tau & & \Delta & & \Delta & \\
 \text{X} & & & 180^\circ_{\phi_2} & & 90^\circ_{\phi_3} & & 180^\circ_{\phi_4} & & \text{Acquire}
 \end{array}$$

which is that most widely used. The X signal obtained depends on Δ and on the multiplicity of X: this is the basis of INEPT spectral editing in ^{13}C NMR.

INEPT has now been partially supplanted by DEPT⁸ (distortionless enhancement by polarization transfer), which for spectral editing purposes is less affected by variations in $^1J(\text{C}, \text{H})$. DEPT also yields in-phase proton coupled X multiplets with normal intensity ratios, whereas the basic INEPT sequence gives antiphase multiplets (refocused INEPT gives normal multiplet patterns if a proton 90° purging pulse is added). The pros and cons of different editing methods are discussed by Sørensen and Jakobsen.³ DEPT is half as long again as INEPT, which makes it less suitable for systems that have short transverse relaxation times T_2 . The most widespread current use of INEPT is as a building block in more complex experiments. Two-dimensional (2D) and three-dimensional (3D) NMR experiments frequently need broadband transfer of polarization between nuclei; INEPT is usually preferred to DEPT for this purpose, partly because of its lower T_2 losses. Popular examples include relayed heteronuclear shift correlation⁹ and the HSQC experiment.¹⁰

2 HISTORICAL REVIEW

Before the introduction of pulsed methods, a number of different techniques were used for the transfer of polarization between heteronuclei. These included selective population

transfer¹¹ (SPT), which may be regarded as a frequency-selective precursor of INEPT and DEPT, and Hartmann–Hahn transfer.¹² SPT uses selective pulses to transfer polarization to one X nucleus at a time. The basic Hartmann–Hahn experiment, while very effective in solid state NMR, is of little practical use in liquid state NMR because it requires very accurate matching of proton and X rf fields. Although some useful progress was made in its application to liquids¹³ in the 1970s, such methods did not find significant application until the recent introduction¹⁴ of methods based on composite pulse decoupling sequences.

INEPT was first conceived as a tool for improving the sensitivity of low- γ nuclei, following the observation that the good sensitivity of the 2D heteronuclear correlation experiment arose in part from the transfer of spin state polarization from protons to ^{13}C . The first experiments used a short extra delay off resonance to achieve a proton 90° phase shift; after a phase shifter was constructed, both the five pulse and the refocused seven-pulse INEPT experiment were tried. Only the results from the five-pulse sequence were published, because the refocused sequence showed poorer signal enhancement. The acronym INEPT was chosen as a reaction against the fashion for burdening experiments with names which promised more than they could deliver; this policy continued with INADEQUATE.

Perhaps the most important contribution to the application of INEPT came from Doddrell and Pegg,¹⁵ who showed that the 2Δ dependence of the enhanced X signal on multiplicity (see Figure 3 below), up to then simply regarded as a nuisance, which required the use of a compromise value for the final delay Δ_2 in 2D shift correlation, was the basis of an efficient means of determining ^{13}C multiplicities. Until then, multiplicities had generally been determined using coherent off-resonance decoupling, which sacrifices sensitivity and is susceptible to artifacts. The INEPT method gives a sensitivity comparable to that of conventional proton-decoupled ^{13}C NMR, and in systems with uniform one-bond couplings gives clean and unambiguous results. Where a range of J values is present, DEPT and SEMUT give cleaner results; the GL versions of these sequences are still less vulnerable to J variation.³

Many variations on and refinements of INEPT have been described. The concept of INEPT can be extended to transfer between groups of non-spin- $\frac{1}{2}$ nuclei.¹⁶ INEPT can provide signal enhancement for relaxation time measurements¹⁷ or for experiments such as INADEQUATE.¹⁸ The antiphase nature of the intermediate state between the proton 90°_y and X 90° pulses allows INEPT to be used to probe specific heteronuclear relaxation pathways.¹⁹ The sensitivity of INEPT to mismatch between the coupling constant $J(\text{X}, \text{H})$ and the delays τ and Δ can be reduced by replacing the modulated echoes of the basic sequence with composite bilinear rotations.^{4,20} INEPT can be made selective for a given range of chemical shifts, for example by using soft pulses for the protons.²¹

3 THEORY

3.1 Vector Picture Description

The original INEPT experiments were developed using simple ideas based on Bloch vector pictures; the more

recent introduction of product operator methods²² has greatly simplified the rigorous description of multiple pulse NMR experiments in weakly coupled spin systems. The original description of INEPT gives a useful insight into the mechanism of the experiment, as well as an illustration of the strengths and weaknesses of the vector picture approach. For simplicity, the nuclei involved here will be assumed to be ^{13}C and protons; the arguments apply equally to any pair of spin- $\frac{1}{2}$ nuclei.

Consider a ^1H – ^{13}C two-spin system CH, in which there is a scalar coupling $J(\text{C}, \text{H})$. Suppose that the spin system initially has the normal Boltzmann polarization for protons, but no polarization for ^{13}C (this could easily be achieved by saturating the ^{13}C transitions; in practice, phase cycling suppresses signals from this source). There will be a fractional population difference $P_{\text{H}} = \gamma_{\text{H}}B_0/(2kT)$ across the proton transitions, where B_0 is the static magnetic field, k is Boltzmann's constant, and T is the absolute temperature. The relative populations of the spin states are as shown on the energy level diagram in Figure 1(a). The ^{13}C and proton spectra would then be as shown in Figure 1(b): no signal for ^{13}C , and two signals (the ^{13}C satellites) for protons, one for the molecules in which the ^{13}C spin is in state α , and one for the other half in which the carbon is β .

Suppose a selective 180° pulse is applied to the ' β ' satellite (transition 34). This will exchange the populations of the spin states $\beta\alpha$ and $\beta\beta$, inverting the proton β satellite, but also changing the population differences across the two carbon transitions. The effect on the carbon spectrum [Figure 1(c)] is to give two antiphase signals, again one for molecules with proton α and one for proton β . The intensities of these carbon signals are determined by the initial proton population difference P_{H} , and hence are four times those of normal ^{13}C signals (assuming no Overhauser enhancement). This SPT/SPI experiment serves two purposes: it shows which ^{13}C is coupled to the proton inverted, and it gives ^{13}C signals with fourfold enhanced intensity.

INEPT uses a modulated proton spin echo to give the same effect of inverting one satellite, but for all CH_n groups in a sample, irrespective of proton chemical shift. Starting once again from a state in which the spin system has Boltzmann polarization for protons but none for ^{13}C , consider the effect of the basic INEPT sequence on the two proton magnetizations, viewed in a frame of reference rotating at the proton transmitter

Figure 1 Energy level diagram (a) and stick spectra for a CH spin system, (b) before and (c) after application of a selective 180° pulse to transition 34

frequency (Figure 2). The first proton 90°_x pulse rotates the magnetizations from their equilibrium position pointing along the $B_0(z)$ direction to lie along the $-y$ axis (for consistency with the product operator description that follows, a right-handed axis convention will be used here). After a time $\tau = 1/[4J(C,H)]$, the two vectors have precessed apart by 90° [Figure 2(b)]; their positions in the transverse plane depend on the frequency difference between the proton chemical shift and the proton transmitter. The proton 180°_x pulse reflects the positions of the α and β vectors about the xz plane, just as in a normal spin echo, but the carbon 180° pulse then interchanges the labels of the α and β satellites [Figure 2(c)], since a 180° pulse interchanges α and β spin states. The second delay τ causes the gap between the two proton magnetizations to widen to 180° , but the refocusing effect of the proton 180° pulse ensures that the two magnetizations end up aligned along the $\pm x$ axes of the proton rotating frame irrespective of the chemical shift [Figure 2(d)].

The proton 90°_y pulse then rotates the β magnetization down to the $-z$ axis, and the α magnetization back up to the $+z$ axis [Figure 2(e)]: the effect of the sequence so far is the same as that of the selective proton 180° pulse in the SPT experiment, except that the effect achieved is independent of the proton shift. The carbon 90° pulse produces two antiphase transverse carbon magnetizations, with intensities four times those of normal carbon signals. In the refocused INEPT experiment, a second modulated spin echo period $\Delta = 180^\circ_H, 180^\circ_X - \Delta$ allows the two ^{13}C magnetizations to precess back into phase, aligning along the x axis of the ^{13}C rotating frame of reference at the end of the second Δ delay for $\Delta = 1/[4J(C,H)]$. The same logic may be applied to CH_2 and CH_3 spin systems, leading to the conclusion that the basic INEPT sequence generates ^{13}C multiplet patterns of a 1:0: -1 triplet for CH_2 , and a 1:1:-1:-1 quartet for CH_3 . The effect of the final refocusing delay in the refocused INEPT sequence depends on the multiplicity: for CH_2 groups the antiphase signals come back into phase for $\Delta = 1/[8J(C,H)]$, but for CH_3 there is no value of Δ for which all four magnetizations are in phase. The different behavior of CH , CH_2 , and CH_3 groups as a function of Δ is explored in Section 3.2, and forms the basis of the use of INEPT for ^{13}C spectral editing.

The vector description of the action of INEPT given above is self-consistent, and predicts correctly the results of INEPT experiments in simple CH_n groups, and the dependence of those results on parameters such as delays and pulse flip angles. The limitations of the approach become clear if the order in which the proton and ^{13}C 90° pulses are applied is inverted. This has no effect on the outcome of the experiment (the two pulses may be applied in either order, or indeed simultaneously), but the effect of applying a 90° ^{13}C pulse to a CH spin system with antiphase proton magnetizations is to generate heteronuclear multiple quantum coherence, and cannot be described using simple vector pictures. The simplest rigorous way to describe pulsed experiments on weakly coupled spin systems is by using the product operator formalism.²²

3.2 Product Operator Description

In the product operator formalism the state of a spin system is represented as a linear combination of products of the spin

Figure 2 Vector description of the basic INEPT sequence for a CH spin system, showing the product operator representations of each state

operators $\hat{I}_x$, $\hat{I}_y$, and $\hat{I}_z$. For a CH group, let S denote carbon and I proton; the initial state in which only the protons are polarized is then $\hat{I}_z$. The initial polarization is once again $P_H = (\gamma_H B_0 / 2kT)$; thus if the signal were measured immediately after the 90° pulse, the proton y magnetization would be

$$M_y^H = N\gamma_H \text{Tr}\{-P_H \hat{I}_y \hat{I}_y\} = -\frac{N\gamma_H^2 B_0}{4kT} \quad (1)$$

where N is the number of spin systems per unit volume. In the basic INEPT sequence this proton y magnetization goes on to evolve under the proton chemical shift and the ^1H - ^{13}C scalar coupling (the intermediate states are indicated in Figure 2), to form the modulated spin echo $-2\hat{I}_x \hat{S}_z$ at time

2τ . The proton 90°_y pulse converts this to $2\hat{I}_z\hat{S}_z$, followed by the carbon 90°_x pulse which converts the J -ordered state [Figure 2(e)] into antiphase carbon y magnetization $-2\hat{I}_z\hat{S}_y$. In contrast to the problems encountered with the vector treatment, interchanging the proton and carbon 90° pulses here does not affect the argument: the sequence of states just changes from $-2\hat{I}_x\hat{S}_z \rightarrow 2\hat{I}_z\hat{S}_z \rightarrow -2\hat{I}_z\hat{S}_y$ to $-2\hat{I}_x\hat{S}_z \rightarrow 2\hat{I}_x\hat{S}_y \rightarrow -2\hat{I}_z\hat{S}_y$, where the intermediate state is a mixture of heteronuclear zero and double quantum coherence rather than a J -ordered state. Extending the basic sequence to the refocused INEPT sequence adds a further modulated spin echo $\Delta - 180^\circ_H, 180^\circ_X - \Delta$, converting the antiphase carbon doublet $-2\hat{I}_z\hat{S}_y$ into the in-phase signal $\hat{S}_x$ when $\Delta = 1/[4J(\text{C,H})]$. For an arbitrary delay Δ the final state at the end of the refocused sequence is

$$-2\hat{I}_z\hat{S}_y \cos[2\pi\Delta J(\text{C,H})] + \hat{S}_x \sin[2\pi\Delta J(\text{C,H})] \quad (2)$$

When proton (I) decoupling is used during measurement of the carbon (S) free induction decay, only the second term is observed. By analogy with equation (1) above, the net ^{13}C magnetization produced is

$$M_x^C(\Delta) = N\gamma_C \text{Tr}\{\hat{S}_x P_H \hat{S}_x\} = \frac{N\gamma_C\gamma_H B_0}{4kT} \sin[2\pi\Delta J(\text{C,H})] \quad (3)$$

which is enhanced by a factor γ_H/γ_C compared with the normal signal.

For CH_2 and CH_3 groups, denoting the chemically equivalent protons I_1, I_2 and I_1, I_2, I_3 respectively, the basic INEPT sequence yields the states $-2(\hat{I}_{1z} + \hat{I}_{2z})\hat{S}_y$ and $-2(\hat{I}_{1z} + \hat{I}_{2z} + \hat{I}_{3z})\hat{S}_y$. The refocused sequence for arbitrary Δ gives

$$\hat{S}_x \sin 2\theta - 2(\hat{I}_{1z} + \hat{I}_{2z})\hat{S}_y \cos 2\theta + 4\hat{I}_{1z}\hat{I}_{2z}\hat{S}_x \sin 2\theta \quad (4)$$

for CH_2 and

$$\begin{aligned} &3\hat{S}_x \cos^2 \theta \sin \theta + 2(\hat{I}_{1z} + \hat{I}_{2z} + \hat{I}_{3z})\hat{S}_y (2\sin^2 \theta \cos \theta - \cos^3 \theta) \\ &+ 4(\hat{I}_{1z}\hat{I}_{2z} + \hat{I}_{1z}\hat{I}_{3z} + \hat{I}_{2z}\hat{I}_{3z})\hat{S}_x (2\cos^2 \theta \sin \theta \\ &- \sin^3 \theta) + 24\hat{I}_{1z}\hat{I}_{2z}\hat{I}_{3z}\hat{S}_y \sin^2 \theta \cos \theta \end{aligned} \quad (5)$$

for CH_3 , where $\theta = 2\pi\Delta J(\text{C,H})$. In all three cases, the effect of using an arbitrary delay τ is simply to multiply the end result by a factor $\sin[2\pi\tau J(\text{C,H})]$.

The net decoupled carbon signals at the end of the refocused INEPT sequence for CH , CH_2 and CH_3 signals are thus

$$M_x^{\text{CH}}(\Delta) = S \sin \theta \quad (6)$$

$$M_x^{\text{CH}_2}(\Delta) = S \sin 2\theta \quad (7)$$

$$M_x^{\text{CH}_3}(\Delta) = 3S \cos^2 \theta \sin \theta = \frac{3}{4}S(\sin \theta + \sin 3\theta) \quad (8)$$

where $S = (N\gamma_C\gamma_H B_0/4kT)$. This dependence of the INEPT enhanced ^{13}C signal on Δ and multiplicity, illustrated in Figure 3, may be exploited for spectral editing by repeating the experiment with delays Δ of $1/[4J(\text{C,H})]$, $2/[4J(\text{C,H})]$, and $3/[4J(\text{C,H})]$. The first gives positive signals for all protonated carbons, the second gives positive signals for CH and zero for

Figure 3 Dependence of the refocused INEPT signal for CH , CH_2 and CH_3 on $\theta = 360\Delta J(\text{C,H})$

CH_2 and CH_3 , and the last gives positive signals for CH and CH_3 and negative for CH_2 . The three resultant spectra S_1 , S_2 , and S_3 may be combined to give separate subspectra for each multiplicity:

$$\left. \begin{aligned} S_{\text{CH}} &= S_2 \\ S_{\text{CH}_2} &= (S_1 - S_3)/2 \\ S_{\text{CH}_3} &= (\sqrt{2}S_1 + \sqrt{2}S_2 - 2S_3)/3 \end{aligned} \right\} \quad (9)$$

In practice it is usual to use least-squares optimization of the coefficients of S_1 , S_2 , and S_3 to minimize cross-talk between the three subspectra.

Where INEPT is to be used to measure enhanced proton coupled spectra, normal multiplet intensity ratios may be restored by adding a 90° purging pulse to the refocused sequence to give the INEPT⁺ sequence:³

$^1\text{H } 90^\circ$	180°	90°_y	180°	90°
X	τ	τ	Δ	Δ
	180°	90°	180°	Acquire

This has the effect of converting all the antiphase terms in equations (2), (4), and (5) above into heteronuclear multiple quantum coherence, leaving only the term in $\hat{S}_x$ observable. For the general case of an $I_n S$ spin system the final observable state is simply $n \sin \theta \cos^{n-1} \theta \hat{S}_x$.

4 APPLICATIONS

4.1 Practical Implementation

Both the basic and refocused INEPT sequences are suitable for routine use. The two main considerations when programming these pulse sequences on a spectrometer are choice of phase cycling, and the need for care with timing of pulses and delays. The primary role of phase cycling is to ensure that only signals from polarization transfer survive time averaging; a secondary aim is to ensure smooth off-resonance behavior by using EXORCYCLE²³ on the two refocusing pulses. Table 1 shows one possible implementation. Care with timing is needed in order to ensure that exact refocusing is obtained from the first modulated echo: any imbalance between the two τ delays, between the first proton 90° pulse and the proton 180° , and between the 180° and the proton 90°_y , will be punished

by extra loss of polarization transfer efficiency off-resonance. Although it is common to apply the pairs of proton and X 90° and 180° pulses simultaneously, with normal rf field strengths this is not necessary provided that the two proton interpulse delays τ and the carbon interpulse delays Δ are kept equal. Calibration of 90° pulses for X and proton is more critical than for single pulse experiments, but 10% accuracy is generally adequate.

It is occasionally recommended that composite 180° pulses be used in experiments such as INEPT. Here it is necessary to distinguish between inversion pulses (the first X 180° and the second proton 180°) and refocusing pulses (the first proton 180° and the second X 180°). Inversion pulses may be replaced by composite 180° pulses with impunity (and with a small improvement in performance). However, if refocusing 180° pulses are replaced by composite pulses it is vital either that constant-phase pulses²⁴ be used, or that the phase shifts introduced by the composite pulses be compensated.²⁵

4.2 Signal Enhancement

Most current applications of the basic and the refocused sequences are to the enhancement of spectra of low- γ nuclei, using polarization from either protons or ^{31}P ; INEPT is especially valuable for nuclei with negative γ , which can show Overhauser 'enhancements' of less than unity. Figure 4 shows the sensitivity improvement obtainable for ^{15}N in a small cyclic peptide, gramicidin S. Polarization transfer is particularly helpful in the measurement of proton coupled X spectra, although intensity anomalies can occur in spectra with strong proton-proton coupling. Proton relaxation during acquisition provides an additional time saving; the signal-to-noise ratio gain compared with the normal single pulse X spectrum (without Overhauser enhancement) is approximately $(\gamma_{\text{H}}/\gamma_{\text{X}})\sqrt{(T_1^{\text{X}}/T_1^{\text{H}})}$. The choice of whether to use the basic sequence or the INEPT⁺ sequence depends on the degree of crowding in the coupled X spectrum and on the multiplicities of the nuclei of interest; with overlapping signals or XH_2 groups it is important to have the in-phase multiplets and normal intensity ratios given by INEPT⁺ to avoid signal cancellation, but in less crowded spectra the extra intensity of the outer components of multiplets with the basic sequence can be an advantage.

4.3 Spectral Editing

Figure 5 shows the results of INEPT measurements of the ^{13}C spectrum of menthol using the refocused sequence with a

Figure 4 ^{15}N spectra obtained in 6 h at 11.75 T for a 40 mM solution of gramicidin S in dimethyl sulfoxide- d_6 , obtained using (top) INEPT, and (bottom) single 90° pulses without Overhauser enhancement

Figure 5 Refocused INEPT spectra of menthol at 7.05 T: (a) using delays Δ of 2, 4, and 6 ms; and (b) the same data combined to give CH , CH_2 , and CH_3 subspectra

delay τ of 4 ms and delays Δ of 2, 4, and 6 ms, corresponding to approximate values of $\theta = 360\Delta J(\text{C}, \text{H})$ of 45° , 90° , and 135° . Combining the three experimental spectra using least-squares fitting to optimize the separation into subspectra gives the CH , CH_2 , and CH_3 subspectra of Figure 5(b).

1 INTRODUCTION

The initial publication of the *Encyclopedia of Nuclear Magnetic Resonance* contains a description of several slow magic angle turning (MAT) experiments^{1,2} that have as their antecedent the magic angle hopping (MAH) experiment of Bax, Szverenyi and Maciel.³ The MAT articles are based on the seminal work of Gan⁴ and several subsequent developments that improve the spectral quality. Pulse breakthrough may distort MAT spectra, and the distortion can be minimized with three echo refocusing π -pulses.⁵ Time reversal symmetry in the phase corrected MAT (PHORMAT) enhancement,⁶ eliminates the need for computer shearing of a skewed spectrum arising from the use of combined amplitude and phase modulation in the original MAT experiment. The PHORMAT approach gives a high-quality hypercomplex 2D spectrum with the isotropic shifts along the evolution axis and tensor bands in the acquisition dimension. Unfortunately, PHORMAT suffers, as do all amplitude modulated MAT experiments, from the use of flip back pulses that are costly in the signal-to-noise (S/N) ratio. The 5π -PULSE/MAT experiment⁷ directly improves this situation by leaving the magnetization totally in the xy -plane during the entire evolution period.

Before discussing the phase-modulated 5π -pulse experiments with emphasis on the two most popular variants, basic principles of sample rotation are discussed in Section 2 with a classical formulation of appropriate Bloch equations. A banded-matrix secular equation⁸ is used for characterizing the spinning-sideband amplitudes common to magic angle rotating samples. The approach also processes rotational sideband data to yield principal-shift frequencies. This

classical method is a numerically efficient alternative to Floquet theory⁹ and/or the Bessel functions solutions used by Hertzfeld and Berger.¹⁰ The banded matrix method, in concert with a SIMPLEX minimization procedure, converges rapidly to the principal-shift values used in fitting the time-dependent free induction decays (FID). The fit of time-dependent FID data is considerably more precise than the fit of single peak intensities.

The 5π -PULSE/MAT experiment⁷ is discussed in Section 3. It provides a basis for constructing a two-dimensional FID in which the spectrum is transformed into isotropic shifts along the evolution axis and individual tensor bands along the acquisition axis. Two important variants of 5π -PULSE/MAT, i.e., the five π replicated magic angle turning (FIREMAT)¹¹ and the 2D phase adjusted spinning sidebands (2D-PASS),^{12,13} improve the S/N and yield higher quality spectral resolution in a more time-efficient manner. In a matter of hours, either of these two methods provides 2D spectra on molecules containing 50 or more carbon atoms. The FIREMAT variant is a direct extension of the original 5π -PULSE/MAT technique, whereas the related 2D-PASS approach evolved more from the PASS sideband manipulation experiments of Dixon.¹⁴ Otherwise, both FIREMAT and 2D-PASS share a common starting point at the zero evolution time, $t_e = 0$ and may be explained with the same theoretical machinery.

A useful development in data processing, the technique for importing greater evolution resolution¹⁵ (TIGER) treated in Section 4, may be used to enhance MAT methods. TIGER with MAT data enhances simultaneously the resolution and S/N in the evolution dimension. In contrast to Fourier transform (FT) methods, TIGER is a convolution technique that contracts one of the dimensions of the 2D FIDs of MAT by importing resolution from an associated 1D guide spectrum. TIGER yields a 1D acquisition FID for each nuclear spin that is immediately suited for banded-matrix processing and generally increases the efficiency of data collection by reducing the number of evolution increments, especially in smaller molecules.

FIREMAT (Section 5) includes TIGER but also involves a method for replicating periodic blocks of acquisition FIDs. These replicated blocks of evolution data enhance the resolution and time efficiency of FIREMAT. The creative 2D-PASS (Section 6) approach separates, by sideband order, the magnetization in the evolution dimension. In Section 7, the results of 5π -PULSE (with and without TIGER), FIREMAT, and 2D-PASS (with both FT and fast FT) are compared, and their respective sensitivities and time efficiencies briefly discussed.

2 THE CLASSICAL BANDED-MATRIX SECULAR TREATMENT OF SLOW TURNING SPECTRA

2.1 Bloch's Equation of Motion

Bloch's equation, ignoring relaxation, is given by

$$\frac{d\vec{\mu}_v}{dt} = \vec{\mu}_v \times \gamma_v \vec{B}_0 = -\vec{\Omega}_v \times \vec{\mu}_v \quad (2.1)$$

where $\vec{\mu}_v$ is the magnetic moment of the spin v , and $\vec{\Omega}_v = \gamma_v \vec{B}_0 = -\omega_v(\text{LAB})$ is an angular precession velocity that is

Figure 1 The principal shift axis, turning and laboratory frames for sample rotation

co-linear with $\vec{B}_0$. The Zeeman approximation locks the v th spin to the strong $\vec{B}_0$ lying along the Z-axis in the laboratory or Zeeman frame. Utilizing equation (2.1) in the detection plane yields two differential equations for the counter-rotating vectors:

$$\frac{d\mu_{v+}}{dt} = -i\omega_v(\text{LAB})\mu_{v+}, \quad \frac{d\mu_{v-}}{dt} = +i\omega_v(\text{LAB})\mu_{v-} \quad (2.2)$$

The irreducible representations of the magnetic moment, $\mu_{v\pm}$, in the xy plane are

$$\mu_{v\pm} = \mu_{vx} \pm i\mu_{vy} \quad (2.3)$$

In the absence of a sign for γ_v , component μ_{v+} is selected arbitrarily as the preferred form for the following development. It is an equally simple matter to use μ_{v-} .

2.2 Transformations Between Relevant Chemical Shift Frames

The three frames, given in Figure 1, are necessary to describe the spin precession in a rotating sample. They are the principal axis frames, the slow turning axis frame and the laboratory frame with the turning axis at the magic angle relative to the magnetic field.

An equation for $\omega_v(\text{LAB})$ in the laboratory frame may be given in terms of the zeroth and 2nd rank irreducible shift frequencies,¹⁶ $\omega_0^{(0)}(\text{LAB})$ and $\omega_0^{(2)}(\text{LAB})$, respectively:

$$\omega_v(\text{LAB}) = \frac{1}{\sqrt{3}}\omega_0^{(0)}(\text{LAB}) + \sqrt{\frac{2}{3}}\omega_0^{(2)}(\text{LAB}) \quad (2.4)$$

The spin label, v , is ignored for the moment to reduce the complexity of the expressions. The zero-rank frequency, $\omega_0^{(0)}(\text{LAB}) = \omega_0^{(0)}(\text{PAF}) = \sqrt{3}\omega_{\text{iso}}$, is rotationally invariant in all frames. Only the $m = 0$ projection, $\omega_0^{(2)}(\text{LAB})$, is relevant under the Zeeman approximation for the $l = 2$ second-order irreducible spherical frequencies given in the LAB frame.

The transformations between various reference frames using Wigner rotational matrix terms yield the following:

$$\begin{aligned} \omega_0^{(2)}(\text{LAB}) &= \sum_{n=-2}^{+2} \mathbf{D}_{o,n}^{(2)*}(\phi, \theta, \chi)_{\text{TL}} \omega_n^{(2)}(\text{TURN}) \\ &= \sum_{n=-2}^{+2} \sum_{m=-2}^{+2} \mathbf{D}_{o,n}^{(2)*}(\phi, \theta, \chi)_{\text{TL}} \mathbf{D}_{n,m}^{(2)*}(\alpha, \beta, \gamma)_{\text{PT}} \omega_m^{(2)}(\text{PAF}) \end{aligned} \quad (2.5)$$

where $\omega_{\pm 1}^{(2)}(\text{PAF}) = 0$. Typical Euler angle sets, $(\alpha\beta\gamma)$ and $(\phi\theta\chi)$, are used for the (PAF $\rightarrow$ TURN) and (TURN $\rightarrow$ LAB) transformations denoted in Figure 1 as PT and TL, respectively. Zare¹⁷ discusses the molecular to laboratory expansion, given by equation (2.5), in terms of rotational matrix components, $\mathbf{D}_{n,m}^{(\ell)*}(\alpha, \beta, \gamma)_{\text{PT}}$. It is critical that the correct matrix be used for the forward and reverse transformations between the laboratory and molecular frames. The Wigner rotation matrix that transforms irreducible-shift frequencies from the (LAB $\rightarrow$ TURN) or (TURN $\rightarrow$ PAF) has matrix elements defined by Zare:¹⁸

$$\mathbf{D}_{m,n}^{(\ell)}(\alpha, \beta, \gamma)_{\text{TP}} = e^{-im\alpha} d_{m,n}^{(\ell)}(\beta) e^{-in\gamma} \quad (2.6)$$

The reverse rotational transformation from the PAF, fixed in the molecular frame, to the laboratory TURN frame is accomplished with a rotation matrix that is the inverse of equation (2.6), i.e., the complex conjugate of its transpose. Hence, the $\mathbf{D}_{n,m}^{(\ell)*}(\alpha, \beta, \gamma)_{\text{PT}}$ terms in equation (2.5) are given by

$$\mathbf{D}_{n,m}^{(\ell)*}(\alpha, \beta, \gamma)_{\text{PT}} = \mathbf{D}_{m,n}^{(\ell)-1}(\alpha, \beta, \gamma)_{\text{TP}} = e^{in\gamma} d_{n,m}^{(\ell)}(\beta) e^{im\alpha} \quad (2.7)$$

Note in equation (2.5) the row and column indices conform and specify a matrix multiplication without violating the commutation rules of rotational operators. Differences in conventions have made this topic somewhat perplexing in the literature. Thus, for the convenience of the reader the form of the Wigner rotation matrix, $\mathbf{D}^{(2)*}(\alpha, \beta, \gamma)_{\text{PT}}$, used herein is provided as follows:

$$\mathbf{D}^{(2)*}(\alpha, \beta, \gamma)_{\text{PT}} =$$

$$\begin{bmatrix} \frac{1}{4}e^{-2i\gamma}(1+\cos\beta)^2e^{-2i\alpha} & \frac{1}{2}e^{-2i\gamma}\sin\beta(1+\cos\beta)e^{-i\alpha} & \sqrt{\frac{3}{8}}e^{-2i\gamma}\sin^2\beta & -\frac{1}{2}e^{-2i\gamma}\sin\beta(\cos\beta-1)e^{i\alpha} & \frac{1}{4}e^{-2i\gamma}(1-\cos\beta)^2e^{2i\alpha} & M \\ -\frac{1}{2}e^{-i\gamma}\sin\beta(1+\cos\beta)e^{-2i\alpha} & \frac{1}{2}e^{-i\gamma}(2\cos\beta-1)(1+\cos\beta)e^{-i\alpha} & \sqrt{\frac{3}{2}}e^{-i\gamma}\cos\beta\sin\beta & \frac{1}{2}e^{-i\gamma}(2\cos\beta+1)(1-\cos\beta)e^{i\alpha} & -\frac{1}{2}e^{-i\gamma}\sin\beta(\cos\beta-1)e^{2i\alpha} & -1 \\ \sqrt{\frac{3}{8}}\sin^2\beta e^{-2i\alpha} & -\sqrt{\frac{3}{2}}\cos\beta\sin\beta e^{-i\alpha} & \frac{1}{2}(3\cos^2\beta-1) & \sqrt{\frac{3}{2}}\cos\beta\sin\beta e^{i\alpha} & \sqrt{\frac{3}{8}}\sin^2\beta e^{2i\alpha} & 0 \\ \frac{1}{2}e^{i\gamma}\sin\beta(\cos\beta-1)e^{-2i\alpha} & \frac{1}{2}e^{i\gamma}(2\cos\beta+1)(1-\cos\beta)e^{-i\alpha} & -\sqrt{\frac{3}{2}}e^{i\gamma}\cos\beta\sin\beta & \frac{1}{2}e^{i\gamma}(2\cos\beta-1)(1+\cos\beta)e^{i\alpha} & \frac{1}{2}e^{i\gamma}\sin\beta(1+\cos\beta)e^{2i\alpha} & +1 \\ \frac{1}{4}e^{2i\gamma}(1-\cos\beta)^2e^{-2i\alpha} & \frac{1}{2}e^{2i\gamma}\sin\beta(\cos\beta-1)e^{-i\alpha} & \sqrt{\frac{3}{8}}e^{2i\gamma}\sin^2\beta & -\frac{1}{2}e^{2i\gamma}\sin\beta(1+\cos\beta)e^{i\alpha} & \frac{1}{4}e^{2i\gamma}(1+\cos\beta)^2e^{2i\alpha} & +2 \\ -2 & -1 & 0 & +1 & +2 & n \end{bmatrix} \quad (2.8)$$

The combination of equations (2.4) and (2.5) gives the following frequency expression in the laboratory frame, $\omega(\mathbf{LAB})$, for the various spins,

$$\begin{aligned} \omega(\mathbf{LAB}) &= \frac{1}{\sqrt{3}}\omega_0^{(0)}(\text{PAF}) \\ &+ \sqrt{\frac{2}{3}} \sum_{n=-2}^{+2} \sum_{m=-2}^{+2} \mathbf{D}_{o,n}^{(2)*}(\phi, \theta, \chi)_{\text{TL}} \mathbf{D}_{n,m}^{(2)*}(\alpha, \beta, \gamma)_{\text{PT}} \omega_m^{(2)}(\text{PAF}) \quad (2.9) \end{aligned}$$

The alternative, but equivalent, similarity transformations use the standard directional-cosine matrix¹⁹

$$\mathbf{R}(\alpha, \beta, \gamma)_{\text{PT}} = \begin{bmatrix} \cos\alpha\cos\beta\cos\gamma - \sin\alpha\sin\gamma & \sin\alpha\cos\beta\cos\gamma + \cos\alpha\sin\gamma & -\sin\beta\cos\gamma \\ -\cos\alpha\cos\beta\sin\gamma - \sin\alpha\cos\gamma & -\sin\alpha\cos\beta\sin\gamma + \cos\alpha\cos\gamma & \sin\beta\sin\gamma \\ \cos\alpha\sin\beta & \sin\alpha\sin\beta & \cos\beta \end{bmatrix}$$

to convert the chemical-shift tensor from the PAF into the turning frame and subsequently to the laboratory frames as follows:

$$\begin{aligned} T_{\text{TURN}} &= \mathbf{R}(\alpha, \beta, \gamma)_{\text{PT}} \cdot T_{\text{PAF}} \cdot \mathbf{R}^{-1}(\alpha, \beta, \gamma)_{\text{PT}} \\ T_{\text{LAB}} &= \mathbf{R}(\phi, \theta, \chi)_{\text{TL}} \cdot T_{\text{TURN}} \cdot \mathbf{R}^{-1}(\phi, \theta, \chi)_{\text{TL}} \\ &= \mathbf{R}(\phi, \theta, \chi)_{\text{TL}} \cdot \mathbf{R}(\alpha, \beta, \gamma)_{\text{PT}} \cdot T_{\text{PAF}} \\ &\quad \cdot \mathbf{R}^{-1}(\alpha, \beta, \gamma)_{\text{PT}} \cdot \mathbf{R}^{-1}(\phi, \theta, \chi)_{\text{TL}} \quad (2.10) \end{aligned}$$

$\mathbf{R}^{-1}(\alpha, \beta, \gamma)_{\text{PT}}$ is the transpose of the unitary matrix, $\mathbf{R}(\alpha, \beta, \gamma)_{\text{PT}}$. Application of equation (2.10) yields the same expression for $\omega(\mathbf{LAB})$ (i.e., the [3,3] term in T_{LAB}) as obtained for the Wigner rotation transformations given in equation (2.9) when equation (2.8) is employed.

2.3 Irreducible-Spherical Shift Frequencies and Appropriate Rotational Transformations

The definition of irreducible-spherical shift frequencies¹⁶ in any molecular frame is as follows:

$$\begin{aligned} \omega_0^{(0)}(\text{mol}) &= \frac{1}{\sqrt{3}}[\omega_{zz} + \omega_{xx} + \omega_{yy}] = \sqrt{3}\omega_{\text{iso}} \\ \omega_0^{(2)}(\text{mol}) &= \sqrt{\frac{2}{3}}\left[\omega_{zz} - \frac{1}{2}(\omega_{xx} + \omega_{yy})\right] = \sqrt{\frac{3}{2}}[\omega_{zz} - \omega_{\text{iso}}] \\ \omega_{\pm 1}^{(2)}(\text{mol}) &= \frac{1}{2}[\mp(\omega_{xz} + \omega_{zx}) - i(\omega_{yz} + \omega_{zy})] \\ \omega_{\pm 2}^{(2)}(\text{mol}) &= \frac{1}{2}[(\omega_{xx} - \omega_{yy}) \pm i(\omega_{xy} + \omega_{yx})] \quad (2.11) \end{aligned}$$

These irreducible frequencies in radians per second express the symmetrical portion of the chemical shift tensor. Division by 2π converts equation (2.11) from radians per second to cps or Hz. In the PAF tensor only diagonal elements exist and equation (2.11) reduces to the zero-rank isotropic frequency and three ($m = -2, 0, 2$) of the five second-rank frequencies, respectively, as follows:

$$\omega_0^{(0)}(\text{PAF}) = \sqrt{3}\omega_{\text{iso}} \quad (2.12)$$

with the second-rank frequencies given in vector form, i.e.,

$$\vec{\omega}^{(2)} = \begin{bmatrix} \omega_{-2}^{(2)}(\text{PAF}) \\ \omega_{-1}^{(2)}(\text{PAF}) \\ \omega_0^{(2)}(\text{PAF}) \\ \omega_1^{(2)}(\text{PAF}) \\ \omega_2^{(2)}(\text{PAF}) \end{bmatrix} = \begin{bmatrix} \frac{1}{2}\omega_{\text{span}} \\ 0 \\ \sqrt{\frac{2}{3}}\omega_{\text{acent}} \\ 0 \\ \frac{1}{2}\omega_{\text{span}} \end{bmatrix} \quad (2.13)$$

where $\omega_{\text{iso}} = (1/3)(\omega_{11} + \omega_{22} + \omega_{33})$, $\omega_{\text{acent}} = \omega_{22} - (1/2)(\omega_{11} + \omega_{33})$ and $\omega_{\text{span}} = (\omega_{11} - \omega_{33})$. The notations iso, acent, and span are used for isotropic, acentricity, and span, respectively. Note that the ω_{zz} direction is best identified with the ω_{22} principal frequency and the ω_{xx} and ω_{yy} terms with ω_{11} and ω_{33} principal frequencies, respectively. The ω_{11} , ω_{22} and ω_{33} are the principal chemical shift frequencies. In Mason's²⁰ convention for symmetry combination of tensor terms, iso and span are the same as used herein, but acent, equal to the product of Mason's skew times the span, is preferred in this work. These proposed simple irreducible forms are very useful with Wigner rotation matrices because they exhibit the symmetry features of irreducible tensors while skew and the traditional asymmetry parameter are ratios of irreducible forms.

It is convenient to evaluate the relevant part of the rotational matrix RTL using values of the Euler angles: $\phi, \theta = \theta_m, \chi = 0$. The selection of χ equal to zero, while arbitrary, expresses the cylindrical symmetry of the $\vec{B}_0$ magnetic field in the laboratory frame. Thus,

$$\mathbf{D}_{0,0}^{(2)*}(\phi, \theta_m, \chi)_{\text{TL}} = d_{0,0}^{(2)}(\theta_m) = \frac{1}{2}(3\cos^2\theta_m - 1) = 0$$

$$\begin{aligned}
\mathbf{D}_{0,\pm 1}^{(2)*}(\phi, \theta_m, \chi)_{\text{TL}} &= d_{0,\pm 1}^{(2)}(\theta_m) e^{\pm i\phi} \\
&= \pm \sqrt{\frac{3}{2}} \sin \theta_m \cos \theta_m e^{\pm i\phi} = \pm \sqrt{\frac{1}{3}} e^{\pm i\phi} \\
\mathbf{D}_{0,\pm 2}^{(2)*}(\phi, \theta_m, \chi)_{\text{TL}} &= d_{0,\pm 2}^{(2)}(\theta_m) e^{\pm 2i\phi} \\
&= \sqrt{\frac{3}{8}} \sin^2 \theta_m e^{\pm 2i\phi} = \sqrt{\frac{1}{6}} e^{\pm 2i\phi} \quad (2.14)
\end{aligned}$$

Here, $\cos^2 \theta_m = 1/3$ and $\sin^2 \theta_m = 2/3$. The transformation matrix from the TURN frame to LAB frame now is limited to the row vector,

$$\mathbf{D}_{0,n(-2,-1,0,+1,+2)}^{(2)*}(\phi, \theta, \chi)_{\text{TL}} = \left[\sqrt{\frac{1}{6}} e^{-2i\phi} \quad -\sqrt{\frac{1}{3}} e^{-i\phi} \quad 0 \quad +\sqrt{\frac{1}{3}} e^{i\phi} \quad \sqrt{\frac{1}{6}} e^{+2i\phi} \right] \quad (2.15)$$

Note that χ drops out of equation (2.15) because of the cylindrical symmetry in the magnetic field. While the generalized $\mathbf{D}^{(2)*}(\phi, \theta, \chi)_{\text{TL}}$ Wigner rotation matrix is a 5×5 matrix, only the middle row of the matrix, $\mathbf{D}_{0,n(-2,-1,0,+1,+2)}^{(2)*}(\phi, \theta, \chi)_{\text{TL}}$, is relevant to the angular precession frequency in the Zeeman approximation. This simplification in the mathematics arises whenever $\vec{B}_0$, the static magnetic field, dominates all other interactions and defines the Z-axis as the relevant laboratory direction for the angular precession frequency, $\omega_v(\text{LAB})$.

The summations in equation (2.9) over n and m express a $(1 \times 5) \cdot (5 \times 5) \cdot (5 \times 1)$ matrix multiplication of the matrices contained in equations (2.15), (2.8), and (2.13). Thus,

$$\begin{aligned}
\omega_v(\text{LAB}) &= \omega_{\text{iso}} \\
&+ \sqrt{\frac{2}{3}} \left[\sqrt{\frac{1}{6}} e^{-2i\phi} \quad -\sqrt{\frac{1}{3}} e^{-i\phi} \quad 0 \quad +\sqrt{\frac{1}{3}} e^{i\phi} \quad \sqrt{\frac{1}{6}} e^{+2i\phi} \right] \cdot \\
&\left[\begin{array}{ccccc} \frac{1}{4} e^{-2i\gamma} (1 + \cos \beta)^2 e^{-2i\alpha} & (\dots) & \sqrt{\frac{3}{8}} e^{-2i\gamma} \sin^2 \beta & (\dots) & \frac{1}{4} e^{-2i\gamma} (1 - \cos \beta)^2 e^{2i\alpha} \\ -\frac{1}{2} e^{-i\gamma} \sin \beta (1 + \cos \beta) e^{-2i\alpha} & (\dots) & \sqrt{\frac{3}{2}} e^{-i\gamma} \cos \beta \sin \beta & (\dots) & -\frac{1}{2} e^{-i\gamma} \sin \beta (\cos \beta - 1) e^{2i\alpha} \\ (\dots) & (\dots) & (\dots) & (\dots) & (\dots) \\ \frac{1}{2} e^{i\gamma} \sin \beta (\cos \beta - 1) e^{-2i\alpha} & (\dots) & -\sqrt{\frac{3}{2}} e^{i\gamma} \cos \beta \sin \beta & (\dots) & \frac{1}{2} e^{i\gamma} \sin \beta (1 + \cos \beta) e^{2i\alpha} \\ \frac{1}{4} e^{2i\gamma} (1 - \cos \beta)^2 e^{-2i\alpha} & (\dots) & \sqrt{\frac{3}{8}} e^{2i\gamma} \sin^2 \beta & (\dots) & \frac{1}{4} e^{2i\gamma} (1 + \cos \beta)^2 e^{2i\alpha} \end{array} \right] \cdot \left[\begin{array}{c} \frac{1}{2} \omega_{\text{span}} \\ 0 \\ \sqrt{\frac{2}{3}} \omega_{\text{acent}} \\ 0 \\ \frac{1}{2} \omega_{\text{span}} \end{array} \right] \quad (2.16)
\end{aligned}$$

The null terms arising in the two outer vectors greatly simplifies the result of multiplying the three matrices (a vector, a square matrix, and a vector) found in equation (2.16). Thirteen of the 25 terms in the 5×5 matrix are nonvanishing, but they become irrelevant due to the null terms in the TL transformation and in the PAF irreducible principal-frequency vector.

2.4 Precession Frequency Dependency on Transformation Angles

Consideration of the first matrix multiplication in equation (2.16) makes it immediately obvious that the overall transformation depends only on the sum of $(\phi + \gamma)$. Therefore, it is possible to subsume ϕ and γ into a single angle identified

with the mechanical rotation of the sample.²¹ Apportioning $(\phi + \gamma)$ into pre-pulse and post-pulse periods divides the angle into useful time-independent and time-dependent components. A sudden approximation at zero-time, $t = 0$, is invoked for the B_1 pulse that nutates the magnetic spin into the xy -observing plane. The $(\phi + \gamma)$ angle therefore divides into an orientational lattice angle, γ_o , and a time-dependent angular term, $\gamma_t = \omega_r t$, where the mechanical rotational frequency is given by ω_r . Thus,

$$(\phi + \gamma) = \gamma_o + \gamma_t = \gamma_o + \omega_r t \quad (2.17)$$

The spin identity of unique nuclei now is reintroduced with the index v . Equations (2.16) and (2.17) render $\omega_v(\text{LAB})$ in the following compacted form,²²

$$\omega_v(\text{LAB}) = \sum_{n=-2}^2 W_{v,n}(\alpha, \beta) e^{ni\gamma_o} e^{ni\omega_r t} \quad (2.18)$$

The phase factor, $e^{ni\gamma_o}$, depends on the lattice angle, γ_o , and on the second-rank projection index, n . The explicit form of the $W_{v,n}(\alpha, \beta)$ terms, obtained from the matrix multiplications in equation (2.16), depends on the irreducible shift-frequency parameters, $(\omega_{\text{iso}}, \omega_{\text{acent}}, \omega_{\text{span}})$, for each v spin as follows:

$$\begin{aligned}
W_2(\alpha, \beta) &= \frac{1}{24} [(1 + \cos \beta)^2 e^{i2\alpha} + (1 - \cos \beta)^2 e^{-i2\alpha}] \omega_{\text{span}} \\
&+ \frac{1}{6} [\sin^2 \beta] \omega_{\text{acent}}
\end{aligned}$$

$$\begin{aligned}
W_1(\alpha, \beta) &= \frac{\sqrt{2}}{12} [\sin \beta (1 + \cos \beta) e^{i2\alpha} + \sin \beta (\cos \beta - 1) e^{-i2\alpha}] \omega_{\text{span}} \\
&- \frac{\sqrt{2}}{3} [\sin \beta \cos \beta] \omega_{\text{acent}}
\end{aligned}$$

$$W_o = \omega_{\text{iso}}$$

$$\begin{aligned}
W_{-1}(\alpha, \beta) &= \frac{\sqrt{2}}{12} [\sin \beta (\cos \beta - 1) e^{i2\alpha} + \sin \beta (1 + \cos \beta) e^{-i2\alpha}] \omega_{\text{span}} \\
&- \frac{\sqrt{2}}{3} [\sin \beta \cos \beta] \omega_{\text{acent}}
\end{aligned}$$

$$\begin{aligned}
W_{-2}(\alpha, \beta) &= \frac{1}{24} [(1 - \cos \beta)^2 e^{i2\alpha} + (1 + \cos \beta)^2 e^{-i2\alpha}] \omega_{\text{span}} \\
&+ \frac{1}{6} [\sin^2 \beta] \omega_{\text{acent}} \quad (2.19)
\end{aligned}$$

Note that the zero-rank shift frequency, $\omega_0^{(0)}(\text{LAB})$, provides the expression for W_0 , whereas $\omega_0^{(2)}(\text{LAB})$ relates to W_{-2} , W_2 , W_{-1} and W_1 . Substituting equation (2.18) into equation (2.2) and using the μ_+ form, as indicated earlier, gives the following Bloch equation:

$$\frac{d\mu_v(\alpha, \beta, \gamma_o|t)}{dt} = -i \sum_{n=-2}^2 W_{v,n}(\alpha, \beta, \gamma_o) e^{in\gamma_o} e^{in\omega_r t} \mu_v(\alpha, \beta, \gamma_o|t) \quad (2.20)$$

2.5 Powder Averaging of Bloch's Equation of Motion in MAT Experiments

The orientation of all equivalent nuclei in a single crystal, as a function of time, is represented by $(\alpha, \beta, \gamma_o|t)$. Thus, the magnetization of nuclei in microcrystalline powders with identical spatial-orientations is given by the designation $\mu(\alpha, \beta, \gamma_o|t)$. Maricq and Waugh²³ observed in single crystals, with only one molecular orientation, that phase variations appear in the spectral sidebands relative to the center-band phase. These phase variations relate to $e^{in\gamma_o}$, providing the rf observing pulses are synchronized with the angular positions of the rotating sample.

In a microcrystalline sample, the phase factor $e^{in\gamma_o}$, must be powder averaged, thereby resulting in some loss of phase specificity. When equation (2.18) is powder averaged over the γ_o angle, $\mu(\alpha, \beta, \gamma_o|t)$ is converted into an ensemble magnetization, $m_v(\alpha, \beta|t)$. This $m_v(\alpha, \beta|t)$ ensemble consists of the v spins in those crystallites with a common turning axis, which is described by α and β in the PAF. Members of this subset distribute uniformly over the different values of γ_o . Consequently, equation (2.20) becomes

$$\frac{dm_v(\alpha, \beta|t)}{dt} = -i \sum_{n=-2}^2 W_{v,n}(\alpha, \beta) \overline{e^{in\gamma_o}} e^{in\omega_r t} m_v(\alpha, \beta|t) \quad (2.21)$$

2.5.1 Powder Average over γ_o

Focus now turns to the average phase factor, $\overline{e^{in\gamma_o}}$, and its ensemble $m_v(\alpha, \beta|t)$. In an elegant proof, Levitt²⁴ exhibited that the phase factors for the center-band and sidebands were all equal in rotating micro-crystalline powders. Levitt's treatment assumes three constraints. (i) All spins in the $\mu_v(\alpha, \beta, \gamma_o|t)$ subset experience the same *average* Hamiltonian. (ii) The sample rotation takes the sub-ensemble of spins, $\mu_v(\alpha, \beta, \gamma_o|t)$, related to the turning axis through a periodic cycle of resonance frequencies. (iii) The orientations of these $\mu(\alpha, \beta, \gamma_o|t)$ crystallites experience a uniform distribution over γ_o . Postulate (i) defines the subset of spins belonging to the α, β turning axis. The periodic character of $e^{in\gamma_o}$ satisfies (ii). Finally, (iii) specifies an essential feature of a random powder to give uniform mathematical averaging of the phase factor around the rotational path. The uniform angular probability leads to the following expression:

$$\int_0^{2\pi} P(\gamma_o) d\gamma_o = P(\gamma_o) \int_0^{2\pi} d\gamma_o = 1 \quad (2.22)$$

hence $P(\gamma_o) = 1/2\pi$.

If one integrates $e^{in\gamma_o}$ from a to $a + 2\pi$, expressions for the average phase factor are obtained as follows:

$$\begin{aligned} \overline{\exp(in\gamma_o)} &= \exp\left(inP(\gamma_o) \int_a^{a+2\pi} \gamma_o d\gamma_o\right) = \exp\left(\frac{in}{4\pi} [\gamma_o^2]_a^{a+2\pi}\right) \\ &= \exp(in(\pi + a)) = [\exp(i(\pi + a))]^n = (\pm 1)^n \end{aligned} \quad (2.23)$$

The averaged factors reference the phase of the sidebands to the corresponding center-band identified with the zero rank W_0 . The selection of a specific crystallite by the parameter a is totally arbitrary. Thus it is convenient to choose real values for a (e.g., $a = \pi$ or $a = 0$) to give the final term in equation (2.23). For $n = +2$ or -2 the phase factor is always unity, but when $n = +1$ or -1 then the arbitrariness of odd rank projections creeps into the phase factor. Zare has treated this feature at some length.²⁵ The ensemble average of γ_o , given in equation (2.23), is now complete. It is easily shown below that use of either $+1$ or -1 for $\overline{e^{in\gamma_o}}$ will not alter the results of this treatment. In keeping with traditional practices,²⁶ the negative sign for $(\pm 1)^n$ is arbitrarily selected for this development. Equation (2.18) then becomes

$$\begin{aligned} \omega_v(\text{LAB}) &= \sum_{n=-2}^2 (-1)^n W_{v,n}(\alpha, \beta) e^{in\omega_r t} \\ &\equiv \sum_{n=-2}^2 (-1)^n W_{v,n}(\alpha, \beta) e^{in\gamma_i} \end{aligned} \quad (2.24)$$

and equation (2.21) yields

$$\frac{dm_v(\alpha, \beta|t)}{dt} = -i \sum_{n=-2}^2 (-1)^n W_{v,n}(\alpha, \beta) e^{in\omega_r t} m_v(\alpha, \beta|t) \quad (2.25)$$

2.5.2 Solution of the Bloch equation for the $m_v(\alpha, \beta|t)$ Subsystem of Spins

The $e^{in\omega_r t}$ term makes equation (2.25) quite intractable; consequently, an infinite Fourier expansion is used for $m_v(\alpha, \beta|t)$ to provide a numerical solution for equation (2.25):

$$m_v(\alpha, \beta|t) = A \sum_{k=-\infty}^{+\infty} a_{v,k}(\alpha, \beta) e^{-i(\omega_{v,\text{iso}} + k\omega_r)t} \quad (2.26)$$

where A includes arbitrary spectral phase factors, $e^{-\rho}$, and scaling constants such as m_0 . The $a_{v,k}(\alpha, \beta)$ are expansion coefficients for the α, β designated subsystem. Inserting equation (2.26) into equation (2.25) gives the following expressions:

$$\begin{aligned} \frac{dm_v(\alpha, \beta|t)}{dt} &= -iA \sum_{k=-\infty}^{+\infty} (\omega_{v,\text{iso}} + k\omega_r) a_{v,k}(\alpha, \beta) e^{-i(\omega_{v,\text{iso}} + k\omega_r)t} \\ &\equiv -iA \sum_{k=-\infty}^{+\infty} \sum_{n=-2}^2 (-1)^n W_{v,n}(\alpha, \beta) \\ &\quad \times e^{in\omega_r t} a_{v,k}(\alpha, \beta) e^{-i(\omega_{v,\text{iso}} + k\omega_r)t} \end{aligned} \quad (2.27)$$

Equation (2.27) may be simplified by dropping $dm_v(\alpha, \beta|t)/dt$, clearing the common factors, $-iAe^{i\omega_v \text{iso}t}$, and rearranging and collecting the remaining terms to obtain the following:

$$\sum_{k=-\infty}^{+\infty} \sum_{n=-2}^2 \left\{ (\omega_{v,\text{iso}} + k\omega_r) a_{v,k}(\alpha, \beta) e^{-ik\omega_r t} - (-1)^n W_{v,n}(\alpha, \beta) a_{v,k}(\alpha, \beta) e^{-i(k-n)\omega_r t} \right\} = 0 \quad (2.28)$$

Equation (2.28) is multiplied by $e^{i\lambda\omega_r t}$ and integrated over time. The Kronecker delta is used to exploit the orthogonal character of the Fourier expansion terms to give

$$\sum_{k=-\infty}^{+\infty} \sum_{n=-2}^2 \left\{ (\omega_{v,\text{iso}} + k\omega_r) a_{v,k}(\alpha, \beta) \delta_{k,\lambda} - (-1)^n W_{v,n}(\alpha, \beta) a_{v,k}(\alpha, \beta) \delta_{k-n,\lambda} \right\} = 0 \quad (2.29)$$

Equation (2.29) may be placed into a compacted expression by enforcing the various $\delta_{k,\lambda}$ terms, expanding the n index explicitly, and temporarily ignoring the α, β and v designations to reduce complexity. This gives the following set of constrained equations:

$$\sum_{\lambda=-\infty}^{+\infty} \{ W_2 a_{\lambda+2} - W_1 a_{\lambda+1} + \lambda \omega_r a_\lambda - W_{-1} a_{\lambda-1} + W_{-2} a_{\lambda-2} \} = 0 \quad (2.30)$$

Each set of five terms in $n = -2, \dots, +2$ for a constant value of λ becomes linearly independent expressions, and a summation over λ converts equation (2.30) into the following set of simultaneous equations:

$$\begin{array}{ccccccccc} W_{-2}a_{-4} & -W_{-1}a_{-3} & -2\omega_r a_{-2} & -W_1 a_{-1} & +W_2 a_0 & = 0 & \lambda = -2 \\ W_{-2}a_{-3} & -W_{-1}a_{-2} & -\omega_r a_{-1} & -W_1 a_0 & +W_2 a_1 & = 0 & \lambda = -1 \\ W_{-2}a_{-2} & -W_{-1}a_{-1} & +0 & -W_1 a_1 & +W_2 a_2 & = 0, & \text{for } \lambda = 0 \\ W_{-2}a_{-1} & -W_{-1}a_0 & +\omega_r a_1 & -W_1 a_2 & +W_2 a_3 & = 0 & \lambda = 1 \\ W_{-2}a_0 & -W_{-1}a_1 & +2\omega_r a_2 & -W_1 a_3 & +W_2 a_4 & = 0 & \lambda = 2 \end{array} \quad (2.31)$$

The compacted notation for the W_n and a_λ is used for convenience, but it must be remembered that W_n and a_λ terms both include v and the $\alpha\beta$ axis designations. By converting equation (2.31) into a matrix product, this set of simultaneous equations gives the typical secular equation as follows:

$$\begin{bmatrix} \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ W_{-2} & -W_{-1} & -2\omega_r & -W_1 & W_2 & 0 & 0 & 0 & 0 \\ 0 & W_{-2} & -W_{-1} & -\omega_r & -W_1 & W_2 & 0 & 0 & 0 \\ 0 & 0 & W_{-2} & -W_{-1} & 0 & -W_1 & W_2 & 0 & 0 \\ 0 & 0 & 0 & W_{-2} & -W_{-1} & \omega_r & -W_1 & W_2 & 0 \\ 0 & 0 & 0 & 0 & W_{-2} & -W_{-1} & 2\omega_r & -W_1 & W_2 \\ & & & & \dots & \dots & \dots & \dots & \dots \end{bmatrix} \times \begin{bmatrix} \dots \\ a_{-2} \\ a_{-1} \\ a_0 \\ a_1 \\ a_2 \\ \dots \end{bmatrix} = 0 \quad (2.32)$$

Diagonalization of the banded matrix with the Gaussian elimination procedure yields values for the $a_{v,\lambda}(\alpha\beta)$ eigenvectors that encode the $W_{v,n}(\alpha, \beta)$ information for the v th spin. Recall

from equation (2.19) that $W_{v,n}(\alpha, \beta)$ contains the acent and span irreducible spectral parameters and the α, β Euler angles that prescribe the geometric orientation α, β of the turning axis relative to the PAF. The infinite expansion in λ converges quite rapidly once λ times the interval between spinning sidebands exceeds the span of the tensor band. As k and λ are both arbitrary indices in equation (2.29), the solution for $a_{v,\lambda}(\alpha\beta)$ from equation (2.32) converts equation (2.26) into

$$m_v(\alpha, \beta|t) = A \sum_{\lambda=-\infty}^{+\infty} a_{v,\lambda}(\alpha, \beta) e^{-i(\omega_{v,\text{iso}} + \lambda\omega_r)t} \quad (2.33)$$

2.5.3 Powder Averaging over α and β

A final powder average over the α, β turning axes still is needed to compare the results with the acquisition FID. This step is accomplished by solving equation (2.32) for each member of the complete set of spherical surface points defined by α, β . One then must sum $m_v(\alpha, \beta|t)$ over all α, β rotation axes to define $M_v(t)$, the acquisition FID, of the v th spin as follows:

$$M_v(t) = \sum_{\alpha\beta} w_{\alpha\beta} \cdot m_v(\alpha\beta|t) \quad (2.34)$$

The weighting factor, $w_{\alpha\beta}$, for the α, β mechanical turning vector prescribes the fraction of spherical surface area assigned to each α, β rotational axis. Thus, $w_{\alpha\beta}$ are essential to weight the fractional contributions of a surface summation over $a_{v,\lambda}(\alpha\beta)$.

The powder averaging is straightforward as long as one is moving in the forward direction, where known chemical-shift values simulate a rotational pattern. This process involves merely selecting a representative and distributed number of surface points over which the numerical mapping can faithfully convert the shift values into adequate spectral response functions. Such ensemble averaging over α, β affects only the $W_{n=\pm 1, \pm 2}$ terms in equation (2.32). Accordingly, the $a_{v,\lambda}(\alpha\beta)$ values for each subset of spins, properly weighted and designated by α, β are stored in a summation register to give the ensemble average for $M_v(t)$.

Among the first numerical approaches used in such problems was the POWDER method by Alderman et al.²⁷ This method utilizes an octahedral face embedded into one of the PAF octants prescribed by the chemical shift tensor. The equilateral triangular face is readily subdivided to yield the number of points required for convergence. These points also have a specific factor that weights the fraction of surface points subtended in the solid angle of the incremental triangular segment. A numerical method by Lebedev,²⁸ and used by Eden and Levitt,²⁹ is based on a mathematical procedure for averaging physical properties over the surface of a sphere. The machinery, involving spherical-harmonic expansions of the spherical surface, requires the utilization of defined surface points along with appropriate weighting factors. The Utah laboratory has found that the Lebedev method converges rapidly and its sophistication makes it slightly more precise than the POWDER method for the same number of α, β points. However, increasing the number of spherical surface points to achieve more precision in the Lebedev convergence can become somewhat laborious if the set is not

readily available. Conversely, altering the number of surface points is easily achieved in the POWDER method.²⁷ A number of other numerical schemes²⁸ have been used to powder-average α, β surface points, but our laboratory has had experience only with POWDER and the Lebedev approach.

A slightly more challenging problem is the extraction of chemical shift parameters from the rotational bands found for a new nuclear rotational pattern. In this reverse approach, one uses successive iterations, guided by the simplex method, to converge on the best set of tensor-shift parameters to fit the rotational patterns. Initial shift parameters are selected and used with equation (2.32) to obtain an initial set of $a_{v,\lambda}(\alpha\beta)$. These initial FID values are compared with the experimental FID values, and simplex fitting varies the shift parameters until satisfactory convergence is reached between the experimental and computed results. In subsequent iterations, the set of $a_{v,\lambda}(\alpha\beta)$ must be re-scaled by properly weighting with $w_{\alpha\beta}$. As the Gaussian elimination procedure for diagonalizing a banded matrix is efficient, this iterative numerical method for powder averaging α, β orientations achieves convergence with remarkably efficiency even with a modest PC computer.

3 THE 5π -PULSE EXPERIMENT⁷

Figure 2 presents the basic sequence for the 5π -PULSE experiment subdivided into the evolution and acquisition regimes. During the rotor period, T , five π or 180° pulses modulate the developing phases of the magnetization, Φ_j , in the evolution regime. Figure 2 summarizes the respective evolution details rendered in time variables (T, t_e), or in phase angles ($2\pi, \Phi_{j=1,\dots,6}$).

A mixture of γ_i in radians and degrees will be used for clarity and/or compaction of the notation. This use should be clear even if slightly inconsistent. Note the phase modulation in the evolution dimension at T is only dependent on the isotropic shifts of the various nuclear spins.

Figure 2 Carbon channel pulse sequence for the 5π -PULSE experiment. (Adapted from Ref.⁷ with permission)

3.1 Magnetization in the 5π -PULSE Experiment

A standard 2D FID for a multinuclear subsystem of spins has the following general form:

$$m_v(t_e, t_a) = \sum_{v=1}^{N_v} m_o(v) \cdot g_v(t_e) \cdot f_v(t_a) \quad (3.1)$$

The sum over the index v includes the different nuclei in the sample. $m_o(v)$ is the initial magnetization of the v th spin. The time-dependent function, $f_v(t_a)$, expresses the contribution from the v th FID. These functions are digitized and converted into frequency space using FT methods. At $t = T$ the phase accumulation during the evolution period for the v th nucleus is

$$g_v(t_e) = e^{-R_v(T)} e^{i\Phi_v(t_e)} \quad (3.2)$$

The term, $e^{i\Phi_v(t_e)}$, is a periodic phase-angle accumulation factor characterized by the angle, $\Phi_v(t_e)$. Equal pulse offsets, given in Figure 2 for the 1st, 3rd and 5th π pulses, are defined by the evolution time, t_e , on which $\Phi_v(t_e)$ depends. The five π pulses are equally spaced at $t_e = 0$, leaving the phase accumulation, for this specific evolution time, refocused and unaltered at time T . Combining equations (3.1) and (3.2) yields

$$m_v(t_e, t_a) = m_o(v) e^{-R_v(T)} e^{i\Phi_v(t_e)} f_v(t_a) \quad (3.3)$$

The relaxation term, $e^{-R_v(T)}$, in equations (3.2) and (3.3) decreases $m_o(v)$ to an effective magnetization value, $m_o(v) e^{-R_v(T)}$, that obtains when the acquisition FID begins. This decrease results from spin-spin relaxation with an effective rate given by

$$R_v(T) = l \left(\frac{T}{T_{L_v}} \right) + h \left(\frac{T}{T_{G_v}} \right)^2 \quad (3.4)$$

The relaxation constants, T_{L_v} and T_{G_v} , are the respective Lorentzian and Gaussian relaxation times typically used in solid-state studies, and mixing coefficients are l and h .

3.2 The Relationship between Phase Accumulation and the 5π -Pulse Scheme

An analysis of the phase angles in Figure 2 supplies the phase factors associated with the evolution dimension of the 2D spectrum. Table 1 summarizes the accumulation of angular phase due to rotation in the MAT experiment and to the π reflections on $m_v(\alpha, \beta|t)$ found in equation (2.33). The five π pulses are specified in Figure 2.

In this development, the B_1 field lies along the original $m_o(v)$ axis, but any other presumption would only produce

Table 1

j th phase	Developing phase accumulation	
	At the beginning of the j th period	At the end of the j th period
1	0	ϕ_1
2	$-\phi_1$	$\phi_2 - \phi_1$
3	$\phi_1 - \phi_2$	$(\phi_1 + \phi_3) - \phi_2$
4	$\phi_2 - (\phi_1 + \phi_3)$	$(\phi_2 + \phi_4) - (\phi_1 + \phi_3)$
5	$(\phi_1 + \phi_3) - (\phi_2 + \phi_4)$	$(\phi_1 + \phi_3 + \phi_5) - (\phi_2 + \phi_4)$
6	$(\phi_2 + \phi_4) - (\phi_1 + \phi_3 + \phi_5)$	$(\phi_2 + \phi_4 + \phi_6) - (\phi_1 + \phi_3 + \phi_5)$

an arbitrary phase shift that ultimately fails to affect the conclusions. At the end of the evolution period, i.e., $t = T$, the phase-angle accumulation becomes

$$\Phi_v(t_e) = (\Phi_2 + \Phi_4 + \Phi_6) - (\Phi_1 + \Phi_3 + \Phi_5) \quad (3.5)$$

The six phase periods, Φ_j , develop according to the following integrals along the γ_t path:

$$\Phi_j = \int_{t(j-1)}^{t(j)} \omega_v(\text{LAB}|t) dt = \frac{T}{2\pi} \int_{\gamma(j-1)}^{\gamma(j)} \omega_v(\text{LAB}|\gamma_t) d\gamma_t \quad (3.6)$$

where $\omega_v(\text{LAB}|t)$ and $\omega_v(\text{LAB}|\gamma_t)$ are the relevant t or γ_t forms of equation (2.24) for the v th spin. The two forms of integrals in equation (3.6) relate by a conformal change of variables from time to a rotational angle given by

$$\gamma_t = \omega_r t \quad \text{and} \quad dt = \frac{d\gamma_t}{\omega_r} = \frac{T}{2\pi} d\gamma_t \quad (3.7)$$

The constraints imposed by equation (3.7) upon equation (3.6) and by the information and conventions in Figure 2 specify the specific phase-angle expressions as follows:

$$\begin{aligned} \Phi_1 &= \frac{T}{2\pi} \int_0^{\frac{\pi}{3} - \frac{\pi}{3} t_e/T} \omega_v(\text{LAB}|\gamma_t) d\gamma_t \\ \Phi_2 &= \frac{T}{2\pi} \int_{\frac{\pi}{3} - \frac{\pi}{3} t_e/T}^{\frac{2\pi}{3}} \omega_v(\text{LAB}|\gamma_t) d\gamma_t \\ \Phi_3 &= \frac{T}{2\pi} \int_{\frac{2\pi}{3}}^{\pi - \frac{\pi}{3} t_e/T} \omega_v(\text{LAB}|\gamma_t) d\gamma_t \\ \Phi_4 &= \frac{T}{2\pi} \int_{\pi - \frac{\pi}{3} t_e/T}^{\frac{4\pi}{3}} \omega_v(\text{LAB}|\gamma_t) d\gamma_t \\ \Phi_5 &= \frac{T}{2\pi} \int_{\frac{4\pi}{3}}^{\frac{5\pi}{3} - \frac{\pi}{3} t_e/T} \omega_v(\text{LAB}|\gamma_t) d\gamma_t \\ \Phi_6 &= \frac{T}{2\pi} \int_{\frac{5\pi}{3} - \frac{\pi}{3} t_e/T}^{2\pi} \omega_v(\text{LAB}|\gamma_t) d\gamma_t \end{aligned} \quad (3.8)$$

The $\omega_v(\text{LAB}|\gamma_t)$ frequency response function in the laboratory frame, taken from equation (2.24), is modified to separate the zero-rank from the second-rank terms, as follows:

$$\begin{aligned} \omega_v(\text{LAB}|\gamma_t) &= \sum_{n=-2}^2 (-1)^n W_{v,n}(\alpha, \beta) e^{in\gamma_t} \\ &= W_{v,0} + \sum_{n=\pm 1, \pm 2} (-1)^n W_{v,n}(\alpha, \beta) e^{in\gamma_t} \end{aligned} \quad (3.9)$$

The $\omega_v(\text{LAB}|\gamma_t)$ in equation (3.9) is divided into its two parts (i.e., the zero-rank rotationally invariant term, $W_{v,0}$, and four second-rank terms given by the summation of n over ± 1 and ± 2).

3.2.1 The Zero-Rank Term

The phase associated with the zero-rank term, $W_{v,0} = \omega_{\text{iso}}$, of equation (3.9) when substituted into equation (3.8) and in turn into equation (3.5) yields the following:

$$\begin{aligned} \Phi_v(t_e) &= \frac{T\omega_{\text{iso}}}{2\pi} \left\{ -\int_0^{\frac{\pi}{3} - \frac{\pi}{3} t_e/T} d\gamma_t + \int_{\frac{\pi}{3} - \frac{\pi}{3} t_e/T}^{\frac{2\pi}{3}} d\gamma_t - \int_{\frac{2\pi}{3}}^{\pi - \frac{\pi}{3} t_e/T} d\gamma_t \right. \\ &\quad \left. + \int_{\pi - \frac{\pi}{3} t_e/T}^{\frac{4\pi}{3}} d\gamma_t - \int_{\frac{4\pi}{3}}^{\frac{5\pi}{3} - \frac{\pi}{3} t_e/T} d\gamma_t + \int_{\frac{5\pi}{3} - \frac{\pi}{3} t_e/T}^{2\pi} d\gamma_t \right\} \\ &= \frac{T\omega_{\text{iso}}}{2\pi} \left\{ 2\left(-\frac{\pi}{3} + \frac{2\pi}{3} - \pi + \frac{4\pi}{3} - \frac{5\pi}{3}\right) + 2\pi + 2\pi \frac{t_e}{T} \right\} \\ &= \omega_{\text{iso}} t_e \end{aligned} \quad (3.10)$$

This form may now be substituted into equation (3.2) as discussed below.

3.2.2 The Second-rank Terms

Attention is now directed to the second-rank terms (i.e., $n = \pm 1, \pm 2$) of equation (3.9). These components vanish under the symmetry of equation (3.5). It is sufficient to show that any one of the generic terms is zero for all four second-rank terms to vanish. Thus, equations (3.5), (3.6) and any of the $n \neq 0$ components of equation (3.9) gives

$$\begin{aligned} \Phi_{v,n}(t_e) &= \frac{T(-1)^n W_{v,n}(\alpha, \beta)}{2\pi} \\ &\times \left\{ -\int_0^{\frac{\pi}{3} - \frac{\pi}{3} t_e/T} e^{in\gamma_t} d\gamma_t + \int_{\frac{\pi}{3} - \frac{\pi}{3} t_e/T}^{\frac{2\pi}{3}} e^{in\gamma_t} d\gamma_t \right. \\ &\quad \left. - \int_{\frac{2\pi}{3}}^{\pi - \frac{\pi}{3} t_e/T} e^{in\gamma_t} d\gamma_t + \int_{\pi - \frac{\pi}{3} t_e/T}^{\frac{4\pi}{3}} e^{in\gamma_t} d\gamma_t \right. \\ &\quad \left. - \int_{\frac{4\pi}{3}}^{\frac{5\pi}{3} - \frac{\pi}{3} t_e/T} e^{in\gamma_t} d\gamma_t + \int_{\frac{5\pi}{3} - \frac{\pi}{3} t_e/T}^{2\pi} e^{in\gamma_t} d\gamma_t \right\} \end{aligned} \quad (3.11)$$

Upon integrating, one obtains

$$\begin{aligned} \Phi_{v,n}(t_e) &= \frac{T(-1)^n W_{v,n}(\alpha, \beta)}{2\pi i n} \\ &\times \left\{ 2(+e^{in120^\circ} + e^{in240^\circ}) + e^{in0^\circ} + e^{in360^\circ} \right. \\ &\quad \left. + 2(e^{in60^\circ} + e^{in180^\circ} + e^{in300^\circ}) e^{in60^\circ t_e/T} \right\} = 0 \end{aligned} \quad (3.12)$$

Hence, the symmetry of the 5π -pulse sequence results in nullifying the four second-rank terms and in turn suppressing each of the sideband terms. This pulse scheme leaves the 2D spectrum to develop along the evolution direction under the influence of only the isotropic shifts.

3.3 The 2D FIREMAT FID Magnetization

The evolution FID for the v th nucleus is given by substituting equation (3.10) into equation (3.2),

$$g_v(t_e) = e^{-R_v(T)} e^{i\omega_{v,\text{iso}} t_e} \quad (3.13)$$

Figure 3 (a) A contour plot of the 5π -PULSE spectrum of 1,2,3-trimethoxybenzene, and (b) the corresponding ω_{iso} slices through the contour plot. The insert in (a) is a blow-up of a portion in the 1 and 3 methyl patterns to indicate the resolution between M_1 and M_3 . (Reproduced from Ref.⁷ with permission)

which when substituted into equation (3.1) yields an expression for the 2D FID.

$$m_v(t_e, t_a) = \sum_{v=1}^{N_v} m_o(v) e^{-R_v(T)} e^{i\omega_{v,iso} t_e} f_v(t_a) \quad (3.14)$$

Equation (3.14) is now in the standard mathematical form of a typical 2D FID with the acquisition FIDs separated linearly from the isotropic FID. The 2D FT of equation (3.14) yields a high-quality 2D spectrum in the frequency domain of solid 1,2,3-trimethoxybenzene (see Figure 3). Both the contour plot and corresponding slices through the different carbon-tensor bands exhibit representative data from the 5π -PULSE experiment.

3.3.1 The Individual Spin FIDs in the Acquisition Dimension

The acquisition FID, $f_v(t_a)$, is sampled rapidly and extends for a sufficient period for the v th nucleus to yield adequate spectral range and resolution in this dimension. In Figure 3(b) the spinning sideband patterns for the v th nucleus are separated by their isotropic shifts. A trade-off exists between decreasing the magnetization at T (i.e., $t_a = 0$) due to spin relaxation and the need for t_e to be sufficiently long to yield an evolution spectrum of adequate resolution.

4 TIGER PROCESSING OF TWO-DIMENSIONAL NMR SPECTRA

The rather significant compromises, made between S/N and resolution in solid NMR spectra, impact the accuracy of

determining spectral parameters in solid NMR experiments. All Fourier methods experience such difficulties, of course, but solid spectra are particularly sensitive to this trade-off because of relatively rapid spin-spin relaxation in solids compared with liquids. Shortening the length of the evolution sampling periods minimizes loss of magnetization from such relaxation effects and increases the time efficiency of the experiment. Unfortunately, the resolution of the experiment is adversely affected. Early MAT solid-state experiments suffered from detrimental flip back pulses that significantly attenuate the magnetization in the xy plane, but the 5π -PULSE method avoids this problem of flip back pulses in the traditional MAT suite of experiments. However, as implied in Section 3 this method still requires relatively extensive evolution data-tables to achieve high resolution.

The so-called TIGER procedure¹⁵ offers a way to extract high-resolution data from an otherwise truncated evolution data. Conversely, use of more but shorter t_e time increments increases the spectral width and thereby diminishes the incidence of aliasing in the evolution dimension. Such compromises in the t_a dimension are avoided because of the size of the acquisition FID data tables. In the process of achieving this objective with TIGER, the workers at the Utah NMR laboratory rediscovered two important papers by Manassen, Navon, and Moonen,^{30,31} in which an extensive mathematical basis for TIGER is given. The minor differences between TIGER and the work of Manassen et al.^{30,31} primarily reflect the different spectroscopic capabilities common in spectrometers extant at the two different publication times (separated by a decade). Specialists will want to study the complete

mathematical treatments of TIGER contained in these three relevant references.^{15,30,31} TIGER is a general multidimensional method that has potential for enhancing a number of NMR applications, but the space and focus of this article precludes treatments that go beyond how TIGER works in MAT experiments.

4.1 Matrix Form of the FID Expression

Equation (3.14) may be formulated in standard matrix notation by first casting this equation in a form that reflects the digitized arrays encountered in data collection methods. This is done by expressing $t_e = (n_e - 1)\tau_e$ and $t_a = (n_a - 1)\tau_a$, where τ_e and τ_a are the incremental sampling periods in the respective evolution³² and acquisition dimensions. The integer 1 is subtracted from digitization indices, n_e and n_a , to allow t_e and t_a to assume zero values. Thus, the digitizing indices, $n_e = 1, \dots, N_e$ and $n_a = 1, \dots, N_a$, are associated with N_e and N_a that are respectively the total number of evolution and acquisition increments. The ν th spin index is n_ν . The digitized matrices appear as follows:

$$\mathbf{M}(n_e, n_a)_{N_e \text{ by } N_a} = \mathbf{G}(n_e, \nu)_{N_e \text{ by } N_\nu} \cdot \mathbf{F}(\nu, n_a)_{N_\nu \text{ by } N_a} \quad (4.1)$$

where

$$\mathbf{G}(n_e, \nu) = m_o(n_\nu) e^{-R_\nu(T)} e^{i(n_e-1)\omega_{\nu, \text{iso}}\tau_e} \quad (4.2)$$

$$\mathbf{F}(\nu, n_a) = f_\nu([n_a - 1]\tau_a) \quad (4.3)$$

The matrix multiplication in equation (4.1) represents the sum over ν in equation (3.14). In addition, the matrix dimensions, given in equation (4.1), assist in their physical interpretation as a row labeled by ν in $\mathbf{F}(\nu, n_a)$ contains the acquisition contribution to the FID for the ν th spin. Likewise, the ν column in $\mathbf{G}(n_e, \nu)$ specifies the corresponding evolution FID component for the ν th spin. While the individual $\mathbf{G}(n_e, \nu)$ and $\mathbf{F}(\nu, n_a)$ components are not directly measurable in the 5π -PULSE experiment, the 2D digitized components represented by $\mathbf{M}(n_e, n_a)$ are obtained directly in 2D 5π -PULSE experiments.

Manipulating equation (4.1) allows the extraction of $\mathbf{F}(\nu, n_a)$ from $\mathbf{M}(n_e, n_a)$. Multiplying both sides of equation (4.1) by the complex transpose, $\tilde{\mathbf{G}}^*(\nu, n_e)$, yields

$$\begin{aligned} \tilde{\mathbf{G}}^*(\nu, n_e)_{N_\nu \text{ by } N_e} \cdot \mathbf{M}(n_e, n_a)_{N_e \text{ by } N_a} = \\ \{\tilde{\mathbf{G}}^*(\nu, n_e) \cdot \mathbf{G}(n_e, \nu)\}_{N_\nu \text{ by } N_\nu} \cdot \mathbf{F}(\nu, n_a)_{N_\nu \text{ by } N_a} \end{aligned} \quad (4.4)$$

The inverse square matrix $\{\tilde{\mathbf{G}}^*(\nu, n_e) \cdot \mathbf{G}(n_e, \nu)\}^{-1}$, converts equation (4.4) into equation (4.5) and provides the desired $\mathbf{F}(\nu, n_a)$:

$$\begin{aligned} \mathbf{F}(\nu, n_a)_{N_\nu \text{ by } N_a} = \{\tilde{\mathbf{G}}^*(\nu, n_e) \cdot \mathbf{G}(n_e, \nu)\}_{N_\nu \text{ by } N_\nu}^{-1} \\ \cdot \tilde{\mathbf{G}}^*(\nu, n_e)_{N_\nu \text{ by } N_e} \cdot \mathbf{M}(n_e, n_a)_{N_e \text{ by } N_a} \end{aligned} \quad (4.5)$$

Both sides of equation (4.5) generate matrices that are of identical dimensions, N_ν by N_a . Hence, corresponding ν rows identify directly with each other. These $\mathbf{F}(\nu, n_a)$ vectors provide a separated and digitized FID for each of the ν th spins. Hamilton³³ and Graybill³⁴ describe this matrix process as a way to perform a linear regression or a linear least-squares fit in general, and in particular for the FID of each individual spin

in this application. Redundant data, when available, actually improve the mathematical analysis.

The mathematical developments linking equations (4.1) and (4.5) presumes a number of constraints on the equations to render the matrix procedures viable. It is essential that $N_e \geq N_\nu$. The index N_e is the total number of evolution increments and N_ν is the number of different nuclear spins. When $N_e < N_\nu$, the evolution data are insufficient to complete the matrix operations for all nuclear spins (i.e., $\nu = 1, \dots, N_\nu$) and the process fails. If $N_e > N_\nu$, redundancy exists in the evolution data, and the matrix manipulations provide an even better regression or least-squares fit of the data. Should $N_e = N_\nu$, the operations yield solutions for the $\mathbf{F}$ vectors but without the statistical benefit of redundant data. Redundancy reduces the errors in a least-squares analysis. A final constraint on the mathematical manipulations requires the existence of a so-called guide spectrum expressed by $\mathbf{G}(n_e, \nu)$. Further details appear in Section 4.2.

This contraction of the 2D digitized FID data to individual nuclear 1D FIDs, is definitely not an FT procedure. Instead, the process involves more of a convolution method based on linear regression principles used in matrix least-squares computations.

4.2 Fitting the Guide Spectrum

The digitized guide spectra, contained in the $\mathbf{G}(n_e, \nu)$ matrix, starts with a typical isotropic spectrum such as obtained from a MAS high-speed spinning spectrum. Each isotropic peak is simulated and the corresponding digitized vector is placed into the ν th row of the associated $\tilde{\mathbf{G}}^*(\nu, n_e)$ matrix to give

$$\tilde{\mathbf{G}}^*(\nu, N_e) = [\tilde{g}^*(\nu, 1) \cdots \tilde{g}^*(\nu, n_e) \cdots \tilde{g}^*(\nu, N_e)] \quad (4.6)$$

The individual digitized $\tilde{g}^*(\nu, n_e)$ value is the n_e element of the $\tilde{\mathbf{G}}^*(\nu, N_e)$ vector for the ν th spin, and standard matrix methods give $\mathbf{G}(N_e, \nu)$ from the associated matrix, $\tilde{\mathbf{G}}^*(\nu, N_e)$.

Fitting a high-resolution isotropic spectrum (e.g., a MAS spectrum) to $\tilde{\mathbf{G}}^*(\nu, N_e)$ or $\mathbf{G}(N_e, \nu)$ becomes a crucial step in modeling FIDs such as described in equation (4.6). The fitting procedure adjusts the isotropic spectral frequencies and line shapes with a SIMPLEX algorithm until a satisfactory spectral fit is achieved. The isotropic frequencies follow directly from the independent guide spectrum and the line shapes are simulated using both Lorentzian and Gaussian relaxation processes in accordance with equation (3.4).

4.3 Illustration of the TIGER Method

The most instructive drawing in the literature¹⁵ for the TIGER procedure uses as an example the PHORMAT spectrum (a rotational, but dense sideband spectrum) of 1,2,3-trimethoxybenzene (see Figure 4). The TIGER method is general and an additional application of TIGER will be provided as an example of a FIREMAT spectrum in Section 5. Figure 4 provides a graphic illustration on how the isotropic guide spectrum is decomposed into the individual ν th columns of the $\mathbf{G}(N_e, \nu)$ matrix and then used with the 2D FID data to obtain the acquisition FIDs that exhibit the shift-tensor information. In this example, the number of evolution increments was only

Figure 4 TIGER processing of a 2D solid spectrum of 2,6-dimethoxynaphthalene. (a) Typical 2D FT results obtained for the sparse eight evolution increments. (b) The projection of the 2D-frequency spectrum onto the evolution dimension illustrates the very broad lines in this dimension. (c) A sharp CP/MAS isotropic guide spectrum. (d) Individually simulated peaks of the CP/MAS spectrum provide the information for populating the **G** matrix. The simulated peaks involve a regression fit of both the frequency and shapes of the individual lines in the guide spectrum. (e) The de-convoluted individual ν shift-tensor bands. (Reproduced from Ref.¹⁵ with permission)

eight, a number barely more than the six different nuclei in 2,6-dimethoxynaphthalene. This figure illustrates the unusual resolving power of the technique without a high evolution sampling rate that is costly in time. The narrow isotropic line widths imported into the evolution frequency dimension are at least an order of magnitude narrower than the corresponding line widths from a truncated FT of the 2D FID data. While the greater resolution of TIGER data is beneficial because of its discriminating abilities, the sharper line patterns also improve the S/N in the frequency domain.

Figure 4 includes one case of accidental degeneracy in peak B that is readily observable as two tensors in the B spectral band. Note importing the very narrow guide spectrum has the same effect of converting the broad peaks, shown in (b), into sharp frequency responses shown in Figure 4(c) for shift-tensor bands. This high resolution affects the accuracy with which spectral parameters can be determined. The increase in spectral definition and sensitivity is a hallmark of a TIGER processed spectrum.

5 THE FIREMAT VARIANT OF THE 5π -PULSE EXPERIMENT

The FIREMAT extension to the 5π -PULSE experiment uses the same evolution pulse scheme and TIGER processing method as the parent experiment. This new method also employs the pseudo 2D sideband suppression (P2DSS) replication strategy of Gan³⁵ to expand the data in the evolution dimension. By replicating information collected in the acquisition dimension and placing these data into the evolution dimension, the resolution is enhanced considerably along the isotropic shift

axis. Whereas P2DSS collects data only at the rotor's echo position (i.e., 0, T , $2T$, etc.), FIREMAT replicates echoing data blocks found at all digitized increments. This allows one to decrease the number of evolution increments below the number of different nuclei that influences the TIGER method.

5.1 The P2DSS Method³⁵ and Replication of Refocused Spectral Data

The data replication scheme of P2DSS is given in Figure 5. The periodic features of MAT create rotational echoes in both dimensions and allow the data reorganization depicted in Figure 5. The echoes in both dimensions allow isotropic data tables to be populated solely from acquisition magnetization detected at multiples of T .

One may use the 1D string of evolution data along $t_a = 0$ to create a FID for the isotropic dimension. A Fourier transform from time to frequency space yields isotropic spectra that mimic a CP/MAS spectrum except for artifacts introduced by the discontinuous relaxation parameters, represented by the step functions along the right edge of Figure 5. Simulations indicate that sinc-type functions, resulting from these discontinuities, can introduce significant artifacts into the frequency spectrum whenever $T_2 \approx T$. Fortunately, the discontinuities smooth out when $T_2 > T$ and leave the baseline relatively unaffected as indicated in Figure 6.

5.2 The FIREMAT Method with Full Replication of Refocused Spectral Data

The FIREMAT variant¹¹ expands upon the P2DSS approach and digitizes throughout the whole rotor period in accordance with Figure 7. The magnetization experiences rotational

Figure 5 Graphical example of Gan's P2DSS Replication Scheme. The 2D FID is sampled in the acquisition dimension only at the echo position of the rotor. The solid circles represent the actual data. The open circles are replicated data obtained from the measured data and transported as shown in the figure. The right-hand side of the figure schematically represents the attenuation of the echo intensity due to relaxation during one rotation. (Reproduced from Ref.¹¹ with permission)

Figure 6 Sync-type artifacts are due to stepped relaxation discontinuities in the evolution data, but TIGER ameliorates this problem by minimizing the distortions. Note that, unlike true sidebands, the artifacts are dispersive and opposite in phase on each side of the spectral line. (Adapted from Ref.¹¹ with permission)

echoes at $t_a = T, 2T, \dots, nT$, and, with repeated replication, a fully populated 2D evolution array may be obtained from the acquisition data-table. An $N_e \times N_a$ array bounds the size of this 2D data set, except as truncated by the replication process. The right border of Figure 7 again represents the discontinuous relaxation that may introduce spectral artifacts such as found in Figure 6.

Note the 1D string of FIREMAT data points along $t_a = 0$ constitutes the same 1D data used by Gan³⁵ to obtain

Figure 7 Graphical example of the FIREMAT replication scheme. Solid and open circles are actual and replicated data points of the type shown in Figure 5. The discontinuous relaxation intensities are again represented on the right-hand side of the figure. Data at the rotational echo positions and all intermediate positions populates a full 2D FT data table. (Reproduced from Ref.¹¹ with permission)

his P2DSS. While Gan's isotropic spectrum is more of an idiosyncratic construct of a CP/MAS spectrum, it becomes a special kind of 1D guide spectrum in the FIREMAT procedure. The guide, when constituted in this manner, arises directly from the 2D data and thus mitigates artifacts arising from irregularities in the replication step. The irregularities include discontinuous relaxation, correlation effects from repeated use of the same data, and possible abnormalities due to the manner in which the replicated blocks are truncated. Comparisons between single crystal and FIREMAT data fail to reveal significant replication errors.

5.3 FIREMAT Spectra of Erythromycin-A

Figure 8 illustrates the use of the FIREMAT method to obtain a spectrum on the medicinal, erythromycin-A, containing 36 different carbon atoms. The spectral quality and power of this 2D solid state technique is obvious and the time to acquire the data was only 19 h. The large numbers of carbons in erythromycin-A prevent the data from being presented conveniently in a single figure. Thus, the two remaining sp^2 carbons and a structure for erythromycin-A are given independently in Figure 8. Benefit is derived by aliasing the two sp^2 carbons into open spectral regions as the evolution timing increments can be decreased and the time-efficiency enhanced.

6 THE 2D-PASS FORM OF A 5π -PULSE EXPERIMENT

Antzutkin et al.¹² first proposed 2D-PASS by combining strategies used in PASS by Dixon¹⁴ and in those underlying the 5π -PULSE experiment. In the evolution dimension, the 2D-PASS method separates, by spinning sideband order, the 2D FID. As the evolution dimension merely orders the sidebands by rank, this does not affect the high-resolution spectra found in the 2D-PASS approach¹² because all critical information is contained in the extensive acquisition FID. The original 1D-PASS, also a rotating solids experiment, uses only 4π pulses

Figure 8 FIREMAT spectra of Erythromycin A Dihydrate shown from left to right for isotropic shifts and spinning sidebands of (a) sp^3 and (b) sp^2 carbons, respectively. (Reproduced from Ref.¹¹ with permission)

to phase adjust the spinning sidebands. However, if the original PASS approach¹⁴ is adapted to a 2D 4π -PASS scheme, it would involve a variable-duration preparation period thereby introducing nonuniform relaxation. The fifth π -pulse included in 2D-PASS by Antzutkin et al.¹² refocuses the magnetization at a constant evolution period, T , and avoids variable spin relaxation perturbations that would otherwise deteriorate the 2D spectral quality.

6.1 The Postulated Pitch Angle

The 2D-PASS method utilizes a postulated variable pitch angle, Θ_e , or evolution time, t_e , defined in several different ways as follows:

$$\Theta_e = \omega_r t_e = 2\pi \frac{t_e}{T} = 2\pi \frac{n_e - 1}{N_e} \quad (6.1)$$

where ω_r is the slow-turning angular velocity and T is the period of the sample revolution.³⁶ The Θ_e and t_e have been

formulated with linearly displaced evolution increments. The increment index is n_e , and the total number of evolution increments is N_e . To designate the $t_e = 0$ choice for the first increment, the integer 1 is again subtracted from n_e . Unfortunately, values for t_e are not programmed directly into the spectrometer's computer. A mathematical relation, however, relates the five π -pulses in the t_k timing sequence to the postulated Θ_e . Further, each of the five π -pulses is characterized by a time, t_k , or timing angle, θ_k , related to one another as follows: $t_k/T = \theta_k/2\pi$. This so-called pitch angle, Θ_e , is an important mathematical construct, designed to create a proper Fourier frequency conjugate that transforms the FIDs into separated rank-ordered sidebands. Hence,

$$m_v(t_e, t_a) = m_o(v)\Omega(t_e)F(t_a) \quad (6.2)$$

where the evolution phase factor, $\Omega(t_e)$ is given as

$$\Omega(t_e) = e^{-R(T)}e^{im_o t_e} = e^{-R(T)}e^{im\Theta_e} \quad (6.3)$$

$F(t_a)$ is the acquisition FID separated by spinning sideband order. The formulation of Θ_e , in terms of the timing sequence of the π -pulses given by t_k , is represented graphically in Figure 9. This creative construction of Θ_e preserves the symmetry of the sideband information, while conforming to the standard 2D FID format for $m_v(t_e, t_a)$ given in equation (6.2).

6.2 The Relationships between the Pitch Angle and Timing Sequence

The connection between the evolution pitch angle, Θ_e , and the five timing angles, $\theta_{k=1,\dots,5}$, follows the same mathematical machinery with slightly different notations from that used in Section 3.2. (Note $\theta_{k=0} = 0$ and $\theta_{k=6} = 2\pi$). This allows a direct comparison of the 5π -PULSE and 2D-PASS methods. It should be emphasized, however, that the expressions used herein are equivalent to the quintessential equations (28) and (29) of Antzutkin et al.¹² Using a common formalism enables one to appreciate the subtle differences and similarities between the 5π -PULSE and the 2D-PASS methods. The following equations are reproduced for convenience:

$$\Phi_v(t_e) = (\Phi_2 + \Phi_4 + \Phi_6) - (\Phi_1 + \Phi_3 + \Phi_5) \quad (3.5)$$

$$\begin{aligned} \Phi_j &= \int_{t(j-1)}^{t(j)} \omega_v(\text{LAB}|t) dt \\ &= \frac{T}{2\pi} \int_{\gamma(j-1)}^{\gamma(j)} \omega_v(\text{LAB}|\gamma_t) d\gamma_t \end{aligned} \quad (3.6)$$

$$\begin{aligned} \omega_v(\text{LAB}) &= \sum_{n=-2}^2 (-1)^n W_{v,n}(\alpha, \beta) e^{in\gamma_t} \\ &= W_{v,0} + \sum_{n=\pm 1, \pm 2} (-1)^n W_{v,n}(\alpha, \beta) e^{in\gamma_t} \end{aligned} \quad (3.9)$$

Figure 9 The pitch angle, Θ_e , plotted versus the phase displacements, $\theta_{j=1,\dots,5}$, of the five π -pulses needed to refocus different sideband orders in the 2D PASS approach. (Adapted from Ref.¹² with permission)

The integral limits in 2D-PASS are specified by $\gamma(j) = \theta_j$. The total phase accumulation up to the time, t_e , for the nucleus v is indicated by $\Phi_v(t_e)$, and the six corresponding sub-period phase accumulations by $\Phi_{j=1,\dots,6}$ designated by the index j . These phase accumulations, illustrated explicitly in Figure 2 and implied in Figure 9, hold for each independent nucleus, v . The zero-rank, $W_{v,n=0} = \omega_{v,\text{iso}}$, and the second-rank, $W_{v,n=\pm 1, \pm 2}(\alpha, \beta)$, frequency terms are given explicitly in equation (2.19).

The imposed boundary conditions on the timing sequence differ between the 5π -PULSE and 2D-PASS experiments. In Section 3.2 it was noted that the 5π -PULSE timing sequence preserves the $\omega_{v,\text{iso}}$ terms, but the remaining four second-rank terms, $W_{v,n=\pm 1, \pm 2}(\alpha, \beta)$, average to zero. It now is shown how 2D-PASS suppresses by design the $\omega_{v,\text{iso}}$ terms while implementing a spectral feature based on the four $W_{v,n=\pm 1, \pm 2}(\alpha, \beta)$ terms.

6.2.1 The Zero-rank Term

By analogy to the 5π -PULSE development in Section 3.2.1, $\Phi_v(\Theta_e)$ may also be expressed for the zero-rank term in $\Phi_{j=1,\dots,6}$ as follows:

$$\begin{aligned} \Phi_{v,n=0}(\Theta_e) &= \omega_{v,\text{iso}} \frac{T}{2\pi} \left[\left(\int_{\theta_1}^{\theta_2} d\gamma_t + \int_{\theta_3}^{\theta_4} d\gamma_t + \int_{\theta_5}^{2\pi} d\gamma_t \right) \right. \\ &\quad \left. - \left(\int_0^{\theta_1} d\gamma_t + \int_{\theta_2}^{\theta_3} d\gamma_t + \int_{\theta_4}^{\theta_5} d\gamma_t \right) \right] \end{aligned} \quad (6.4)$$

Integrating equation (6.4) yields the following expressions:

$$\Phi_{v,n=0}(\Theta_e) = \omega_{v,\text{iso}} \frac{T}{2\pi} [-2(\theta_1 - \theta_2 + \theta_3 - \theta_4 + \theta_5) + 2\pi] = 0 \quad (6.5)$$

where $\Phi_{v,0}(\Theta_e)$ has been suppressed by setting it equal to zero. From equation (6.5) it becomes a simple matter to suppress the $\omega_{v,\text{iso}}$ by forcing the linear combination of time angles to vanish. Hence, this null condition is used to form one of five constraints in the construction of Θ_e , and is expressed as

$$\begin{aligned} \pi - (\theta_1 - \theta_2 + \theta_3 - \theta_4 + \theta_5) &= 0 \text{ or} \\ t_1 - t_2 + t_3 - t_4 + t_5 &= \frac{1}{2}T \end{aligned} \quad (6.6)$$

The equivalent expression in time follows from $\theta_k = 2\pi(t_k/T)$.

6.2.2 The Second-rank Terms

Attention is now turned to the second-rank terms. As before, it is sufficient to integrate only one of the $n = \pm 1, \pm 2$ terms. Following the logic of Section 3.2.2, the n -labeled second-rank terms becomes

$$\begin{aligned} \Phi_v(\Theta_e) &= (-1)^n W_{v,n}(\alpha, \beta) \\ &\times \frac{T}{2\pi} \left[\left(\int_{\theta_1}^{\theta_2} e^{in\gamma_t} d\gamma_t + \int_{\theta_3}^{\theta_4} e^{in\gamma_t} d\gamma_t + \int_{\theta_5}^{2\pi} e^{in\gamma_t} d\gamma_t \right) \right. \\ &\quad \left. - \left(\int_0^{\theta_1} e^{in\gamma_t} d\gamma_t + \int_{\theta_2}^{\theta_3} e^{in\gamma_t} d\gamma_t + \int_{\theta_4}^{\theta_5} e^{in\gamma_t} d\gamma_t \right) \right] \end{aligned} \quad (6.7)$$

Table 2 Timings for 2D-PASS Experiment Shown in Figure 9 (taken from Ref.¹²)

Evolution increment	Pitch angle $\frac{\Theta_e}{2\pi} = \frac{n_e - 1}{N_e}$	$\frac{\theta_1}{2\pi}$	$\frac{\theta_2}{2\pi}$	$\frac{\theta_3}{2\pi}$	$\frac{\theta_4}{2\pi}$	$\frac{\theta_5}{2\pi}$

13	0.75000	0.14297	0.25808	0.45416	0.56990	0.73085
14	0.81250	0.13504	0.26155	0.45102	0.57998	0.75547
15	0.87500	0.13761	0.27823	0.46188	0.60458	0.78333
16	0.93750	0.14874	0.30343	0.47958	0.63499	0.81011

Evaluating the integrals in equation (6.7) gives the following:

$$\Phi_{v,n}(\Theta_e) = W_{v,n}(\alpha, \beta) \frac{(-1)^n T}{in2\pi} \times [e^0 + e^{2\pi} + 2(-e^{in\theta_1} + e^{in\theta_2} - e^{in\theta_3} + e^{in\theta_4} - e^{in\theta_5})] \quad (6.8)$$

Using definitions given in equations (6.3) and (3.9), the total phase accumulation, $\Phi_v(t_e)$, for the postulated pitch angle is given by

$$\begin{aligned} \Phi_{v,n}(\Theta_e) &= (-1)^p W_{v,n} \frac{T}{2\pi} \int_0^{\Theta_e} e^{iny_t} dy_t \\ &= -W_{v,n} \frac{T}{in2\pi} (e^{in\Theta_e} - 1) \end{aligned} \quad (6.9)$$

Note $(-1)^p$ provides the alternating phase coherency of successive π -pulses (in this case $p = 5$).

Combining equations (6.8) and (6.9) and eliminating common factors yields

$$e^{in\Theta_e} + 1 + 2(-e^{in\theta_1} + e^{in\theta_2} - e^{in\theta_3} + e^{in\theta_4} - e^{in\theta_5}) = 0 \quad (6.10)$$

Five simultaneous equations were obtained from equations (6.6) and (6.10) from which five θ_k values are found for a given value of Θ_e . The four equations ($n = \pm 1, \pm 2$) embodied in equation (6.9) are best separated¹² into $n = 1, 2$ and into real and imaginary components to calculate values for four of the five θ_k constraints that yield each set of $\Theta_e = 2\pi(n_{e-1}/N_e)$ evolution increments. Antzutkin et al.¹² include a simultaneous equation sub-routine (Mathematica³⁷) in their appendix for calculating the five $\theta_k/2\pi$ values that are used to construct Θ_e . Typical timing values are given in Table 2 for the 16 incremented pitch angles in the 2D-PASS experiment.

6.3 2D-PASS Spectra of Ampicillin

The 2D-PASS spectra (both contour and peak plots) for ampicillin¹³ are presented in Figure 10. Note how the data combine in such a way that the evolution dimension contains only rank-ordered sidebands, whereas the acquisition-dimension portrays both isotropic and shift tensor information

of each sideband component. Computer shearing of the 2D spectral data provides the same rotational sideband pattern for a given nucleus, as found in the FIREMAT spectrum given in Figure 8. Considerable benefits in spectral resolution derive from the larger acquisition data tables in 2D-PASS. These advantages mirror the improvements in the FIREMAT spectra due to data replication.

7 COMPARISON OF 5π -PULSE TYPE OF EXPERIMENTS

7.1 Qualitative Comparison of FIREMAT and 2D-PASS Methods

A careful comparison of Figures 2 and 9, at $t_e = 0$, indicates that 2D-PASS and FIREMAT, along with its predecessor 5π -PULSE, should all give equivalent spectral responses at $t_e = 0$. This similarity in the time-zero magnetization for FIREMAT and 2D-PASS suggests, to a first approximation, that these experiments should have comparable S/N. This conclusion has been verified when a constant number of evolution increments is used in both FIREMAT and 2D-PASS data on the same compound.³⁸ Further, the error propagation in the fit of principal shift values revealed no statistically significant difference, providing proper allowance is made for the greater implementation of automation in the FIREMAT data analysis.

FIREMAT includes automated subroutines for the TIGER and Banded-Matrix-SIMPLEX processing of FIDs in the time domain. Considerably more data in regression fits usually enhance the spectral quality. Hence, the extracted shift parameters are improved considerably by time domain fitting of the FIDs. The sensitivity of spectral parameters from 2D-PASS data would also probably benefit from time-domain fitting of the FIDs. The Herzfeld–Berger method¹⁰ is often used to extract the 2D-PASS shift parameters from peak-height measurements that unfortunately fail to take advantage of the increased data found in a time domain FID.

Except for $t_e = 0$, the 2D-PASS and FIREMAT methods diverge in their treatment of the evolution dimension, and a number of differences may affect the time efficiency of the relative experiments. These differences primarily deal with the use of

Figure 10 2D-PASS of ampicillin. (Reproduced from Ref.¹³ with permission)

TIGER and with spectral aliasing in the evolution dimension that may or may not be important depending upon the molecular size and spectral complexity. The spectroscopist's control over these factors is limited to the selection of the turning frequency, $1/T$, and sampling rate, $1/\tau_e$, whether one uses an actual (FIREMAT) or an effective (2D-PASS) value for τ_e , which is the incremental sampling period. Discounting differences in aliasing and the benefits and/or disadvantages of TIGER, the two methods are otherwise essentially the same except for the visual presentation of the spectral results in frequency space.

7.2 Turning Rates, ω_r , Turning Period, T , and Minimum Span, ω_{span} , of the Shift Tensor

At least three spinning bands (the center and a minimum of two sidebands) for each unique nucleus must be collected in order to determine three principal shift-tensor frequencies and/or the corresponding three irreducible shift frequencies: ω_{iso} , ω_{acent} , and ω_{span} . When the turning rate exceeds a value somewhere between $\omega_{\text{span}}/3$ (for axially symmetric tensors) to $\omega_{\text{span}}/2$ (for centro-symmetric tensors), the number of

spinning bands could be less than three. In this instance, it is impossible to determine chemical shift principal values from such a rotation pattern. $\omega_{\text{span}}^{\text{min}}$ is defined as the minimal spectral width for the narrowest tensor, which establishes the maximum rotation rate that will allow all tensors in the sample to be determined simultaneously. The situation of an axially symmetric shift tensor is more restrictive because ω_{iso} is no longer found at the mid-point of the band. In this situation the factor of $1/3$ should be used to specify the maximum turning rate, ω_r^{max} , or minimum turning period, T^{min} . Under these constraints the various quantities are related by

$$\omega_r^{\text{max}} = \left(\frac{2\pi}{T^{\text{min}}} \right) \leq \left(\frac{\omega_{\text{span}}^{\text{min}}}{3} \right) \text{ or } T^{\text{min}} \geq \left(\frac{6\pi}{\omega_{\text{span}}^{\text{min}}} \right) \quad (7.1)$$

Consider a typical methyl chemical-shift ω_{span} of 1500 Hz obtained from a 15 ppm ω_{span} in a 400 MHz proton instrument (i.e., 100 MHz for ^{13}C). This value in equation (7.1) requires that the maximum turning rate, $\omega_r^{\text{max}}/2\pi$, be 500 Hz or less in order to observe at least three sidebands. Slower turning rates further increase the number of sidebands that are beneficial to the precision of the extracted principal shift values.

7.3 Spectral Evolution Resolution, $\omega_{\text{res}}^{\text{evol}}$, Spin-spin Relaxation, T_2 , Evolution Periods, T

Standard FT relationships affecting resolution also govern in the solid state experiments encountered in this article. Thus, the evolution resolution, $\omega_{\text{res}}^{\text{evol}}$, is limited by the spin-spin relaxation time, T_2 , in accordance with

$$\omega_{\text{res}}^{\text{evol}} \cong \left(\frac{1}{T_2} \right) \geq \frac{2\pi}{T^{\text{min}}} \text{ or } T^{\text{min}} \geq 2\pi T_2 \cong \left(\frac{2\pi}{\omega_{\text{res}}^{\text{evol}}} \right) \quad (7.2)$$

When $1/T_2$ is greater than $2\pi/T^{\text{min}}$, the relaxation broadens the rotational sidebands beyond the $\omega_{\text{span}}^{\text{min}}$ of the tensor and it becomes impossible to characterize such tensor bands. Hence, as a practical matter, $\omega_{\text{span}}^{\text{min}}$ is specified by the narrowest shift tensor whose principal values can be measured from the spinning bands. When one or more of the narrower shift tensors is not distinguishable from spherically symmetric tensors due to relaxation limitations, the anisotropic features of the tensor are lost. Careful attention must be given to this problem because both relaxation and rapid rotations that are too fast will exhibit spherical tensor properties. Relaxation in most bio-organic solids, which tend to exhibit considerable internal motion, usually does not limit the anisotropic tensor information for many bio-molecules. Turning the sample too rapidly need not be a problem as this situation is under the control of the spectroscopist.

7.4 Evolution Spectral Widths and the Sampling Rates

To monitor a spectral width in the evolution dimension and avoid aliasing, the evolution sampling-rate, $1/\tau_e$, must be greater than the evolution spectral width, $\omega_{\text{SW}}^{\text{evol}}$, properly converted into Hz. This condition is expressed by

$$\frac{1}{\tau_e} \geq \left(\frac{\omega_{\text{SW}}^{\text{evol}}}{2\pi} \right) \quad (7.3)$$

For the 5π -PULSE experiment, $\omega_{\text{SW}}^{\text{evol}} = \omega_{\text{isoW}}^{\text{evol}}$, the overall width of the isotropic spectrum. Aliasing or resolution in the evolution dimension for 2D-PASS is not of concern. The only issue in 2D-PASS becomes one of the total number of sidebands required to cover the largest tensor band, while maintaining at least three tensor sidebands for the narrowest tensor (see below).

7.5 The Parent 5π -PULSE Experiment

It is a simple matter to calculate a minimal number of evolution increments, $N_e = T/\tau_e$, by multiplying equations (7.1) by (7.3). The inequality is still valid providing the 5π -PULSE experiment is not limited by relaxation as indicated in equation (7.2). In this limit, the following expression is obtained:

$$N_e(5\pi\text{-Pulse}) = \frac{T^{\min}}{\tau_e} \geq \left(\frac{3 \cdot \omega_{\text{isoW}}^{\text{evol}}}{\omega_{\text{span}}^{\min}} \right) \quad (7.4)$$

Further, the required number of evolution increments depends on the number of nuclear spins that must be differentiated with the FID or with TIGER. This expression is given as follows:

$$N_e(5\pi\text{-Pulse}) \geq N_v \quad (7.5)$$

Assuming possible values of $\omega_{\text{isoW}}^{\text{evol}} \approx 150$ ppm and $\omega_{\text{span}}^{\min} \approx 10$ ppm, the number of evolution increments, in the absence of relaxation constraints, would exceed 45 irrespective of the molecular size. Greater efficiency could be realized if $\omega_{\text{isoW}}^{\text{evol}}$ were smaller or if $\omega_{\text{span}}^{\min}$ were to be larger. For example, the more favorable case where $\omega_{\text{isoW}}^{\text{evol}} \approx 80$ ppm and $\omega_{\text{span}}^{\min} \approx 20$ ppm, would require only 12 increments. One can also escape some of the time inefficiencies if a modest amount of aliasing can be tolerated, especially in relatively small molecules where aliasing may be readily identified. Line broadening due to truncating the FID unduly will limit the S/N ratio and the effective resolution of the frequency domain.

7.6 The Parent 5π -PULSE Experiment with TIGER

The introduction of TIGER processing usually leaves the rotational lines narrower and enhances the S/N. The information from the guide spectrum can be used to optimize resolution and avoid aliasing. Sharper lines from the guide spectrum also yield higher peak intensities with a favorable impact on the S/N in the frequency domain. TIGER is especially powerful when the isotropic width and the minimum span are very similar. In this case, very narrow lines obtain with N_e barely larger than N_v , as found in Figure 4. Nonetheless, the TIGER formalism still requires that the minimum number of evolution increments be equal to or greater than the number of nuclear spins in order to obtain the matrix inverse required.³⁹ This situation is quite critical when molecular size increases to 50–100 carbon-13 nuclei for relevant bio-molecules, and one must conform to the expression in equation (7.5). Further, the creation of a suitable guide spectrum is much more difficult when overlapping isotropic peaks found in larger molecules introduces accidental degeneracy into the spectrum.

7.7 The FIREMAT Variant of 5π -PULSE

In the absence of a relaxation limitation, the replication provides efficiency for FIREMAT that no longer depends on number of nuclear spins. The replication scheme used in this method contains sufficient N_e to eliminate the constraint on N_v . The evolution time sampling rate, $1/\tau_e$, still governs aliasing in the evolution dimension and the second term of equation (7.5) still obtains:

$$N_e(\text{FIREMAT}) \geq \left(\frac{3 \cdot \omega_{\text{isoW}}^{\text{evol}}}{\omega_{\text{span}}^{\min}} \right) \quad (7.6)$$

7.8 The 2D-PASS Alternative to 5π -PULSE

The number of sidebands in 2D-PASS needed to span the widest tensor band determines $N_e(2\text{D-PASS})$. The minimal number of sidebands is readily calculated by enforcing at least three sidebands for the narrowest tensor and noting the corresponding impact on the number of sidebands in the widest tensor. Hence, the constraint for 2D-PASS yields the following:

$$N_e(2\text{D-PASS}) \geq \left(\frac{3 \cdot \omega_{\text{SW}}^{\max}}{\omega_{\text{span}}^{\min}} \right) \quad (7.7)$$

where $\omega_{\text{SW}}^{\max}$ is the maximum width of the spectrum, including all of the rank-ordered side bands. To optimize the use of Fast-FT methods with 2D-PASS, it becomes necessary to increase the number of evolution increments to the next higher power of 2 above $N_e(2\text{D-PASS})$ given in equation (7.7). One of the benefits claimed for 2D-PASS is that standard 2D FT methods may be used to secure a frequency domain spectrum. TIGER, it may be argued, benefits the FIREMAT approach.

7.9 Comparison of 2D-PASS and FIREMAT

Abandoning the alleged advantages of using Fast FT methods or TIGER, equations (7.6) and (7.7) identify the factors that primarily differentiate the two methods. As $\omega_{\text{SW}}^{\max}$ and $\omega_{\text{isoW}}^{\text{evol}}$ are very similar, one is left with the conclusion that the two approaches are comparable. There are instances when the maximum spectral span is larger than the spread of isotropic shifts and vice versa. Hence, the two methods are each preferred under different circumstances. The differences that the author's laboratory has found, deal primarily with the efficiencies of fitting time domain FIDs or peak heights in the frequency domain. Use of TIGER can produce enhanced S/N in the frequency domain and favors peak-height fitting. Time domain fitting of FIDs would equalize this advantage. Thus, both FIREMAT and 2D-PASS are sufficiently similar that personal experience likely becomes the dominant factor in choosing between the two approaches. However, both methods have proven sufficiently successful with moderately large bio-molecules to attest to the arrival of 2D solid state methods in chemical studies.

1 INTRODUCTION

In the context of NMR, ‘overtone spectroscopy’ refers to the direct excitation of nuclear spin transitions and coherences and the direct detection of NMR signals at frequencies that are nearly multiples of the Larmor frequency ν_0 . Overtone spectroscopy depends on the excitation and detection of ‘forbidden’ transitions, i.e. transitions that cannot be excited or detected directly in the limit of very strong external dc magnetic fields but that become excitable or detectable directly when the interactions of nuclear spins with the dc field are not very much stronger than the internal nuclear spin couplings. Recent interest in overtone spectroscopy grew out of the work of Bloom and LeGros,¹ who showed that overtone transitions have sufficient intensity in practice to be of experimental utility. Subsequent work^{2,3} showed that overtone spectroscopy has real advantages when applied to solid state NMR measurements of integer-spin nuclei with large quadrupole couplings. Since ^{14}N is the most important nucleus of this type from the standpoint of chemistry and biochemistry, recent work has focused on ^{14}N overtone NMR.

Overtone spectroscopy should be distinguished from multiple quantum spectroscopy. In multiple quantum spectroscopy, one typically applies rf pulses with a carrier frequency close to ν_0 in order to excite nuclear spin coherences with oscillation frequencies that are nearly multiples of ν_0 . The oscillation of these coherences is then detected indirectly through its effect on the single quantum signals near ν_0 . In overtone spectroscopy, the rf carrier frequency is about equal to the oscillation frequency of the coherences, and the oscillation of the coherences is detected directly. Conceptually speaking, overtone spectroscopy can be thought of as a single photon spectroscopy, while multiple quantum spectroscopy can be thought of as a multiple photon spectroscopy. In some cases, the same coherences may be excited and detected either by overtone NMR or by multiple quantum NMR. As a general rule, overtone methods are probably more effective than multiple quantum methods when the nuclear quadrupole splittings exceed 1 MHz.

Figure 1 shows a spin energy level diagram for a spin-1 nucleus such as ^{14}N . A spin-1 nucleus has three possible eigenstates. In the absence of all spin interactions, the three

Figure 1 Spin energy levels for a spin-1 nucleus. The splitting of the energy levels due to a strong magnetic field and the first-order and second-order perturbations of the energy levels due to a quadrupole coupling are shown. (Adapted by permission of the American Chemical Society from R. Tycko and S. J. Opella, *J. Am. Chem. Soc.*, 1986, **108**, 3531)

states are degenerate. The interaction with an external dc field produces three equally spaced energy levels and two allowed, single quantum transitions at frequency ν_0 . A nuclear quadrupole coupling that is weaker than the interaction with the external field perturbs the energy levels. To first order, a quadrupole coupling with coupling constant ν_Q shifts the middle ($m = 0$) level relative to the upper and lower ($m = \pm 1$) levels by an amount $\nu_Q^{(1)}$ proportional to ν_Q . This produces the first-order quadrupole splitting, with single quantum transitions at $\nu_0 \pm \nu_Q^{(1)}$. To second order, the quadrupole coupling additionally shifts the upper and lower levels by amounts $\pm \nu_Q^{(2)}$ proportional to ν_Q^2/ν_0 . This is the second-order quadrupole shift. The single quantum transitions are then at $\nu_0 \pm \nu_Q^{(1)} + \nu_Q^{(2)}$. In addition, the overtone transition at frequency $2\nu_0 + 2\nu_Q^{(2)}$ becomes weakly allowed, producing signals and nutation frequencies proportional to ν_Q/ν_0 in pulsed NMR experiments. Although the overtone signals are intrinsically weaker than the allowed single quantum (or ‘fundamental’) signals, the fact that the overtone spectrum spans a frequency range that is narrower than the single quantum spectrum by a factor of the order of ν_Q/ν_0 makes measurement of the overtone signals substantially more tractable, especially in polycrystalline and noncrystalline solids (where the resonance lines are inhomogeneously broadened powder patterns) and in single crystals with several inequivalent sites. Thus, particularly in ^{14}N NMR, overtone spectroscopy allows NMR signals to be obtained and nuclear relaxation rates to be measured in systems where NMR experiments would otherwise be extremely difficult or impossible. Overtone spectra also contain structural information that is absent in single quantum spectroscopy, through the dependence of the overtone transition moment on the molecular or crystal orientation and on the direction of the applied rf field.

Overtone NMR spectroscopy of spin-1 nuclei is analogous to earlier ‘half-field’ electron paramagnetic resonance (EPR) studies of triplet states,^{4,5} with the nuclear quadrupole coupling taking the place of the electronic spin–spin coupling or zero field splitting. Calculations of lineshapes and transition probabilities carried out for half-field EPR^{6,7} are therefore applicable to overtone NMR of spin-1 nuclei.

2 THEORY

A detailed description of the theory and the implementation of overtone spectroscopy has been given by Tycko and Opella.³ The essential theoretical points follow from consideration of the spin Hamiltonian $\hat{\mathcal{H}}$ for a quadrupolar nucleus with spin $\hat{S}$:

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}_S + \hat{\mathcal{H}}_{rf} \quad (1)$$

$$\hat{\mathcal{H}}_S = -h\nu_0 \hat{S}_z + h\nu_Q [3\hat{S}_z^2 - \hat{S}^2 + \eta(\hat{S}_x^2 - \hat{S}_y^2)] \quad (2)$$

$$\hat{\mathcal{H}}_{rf} = 2\hbar\gamma_S B_1 (\hat{S}_x \cos \theta + \hat{S}_z \sin \theta) \cos(2\pi\nu t + \phi) \quad (3)$$

$\hat{\mathcal{H}}_S$ includes the interaction with the external dc field along z (the Zeeman interaction) and the quadrupole coupling. The principal axes of the quadrupole coupling tensor are $x'y'z'$. ν_Q is defined as $(e^2qQ)/[4S(2S-1)]$. $\hat{\mathcal{H}}_{rf}$ is the interaction with an rf field with amplitude B_1 , frequency ν , phase ϕ , and direction in the xz plane at angle θ to x . γ_S is the nuclear gyromagnetic ratio. In the limit $\nu_0 \gg \nu_Q$, the eigenstates of $\hat{\mathcal{H}}_S$ are simply the eigenstates of S_z , i.e. $\{|m\rangle\}$. When this limit does not apply, but $\nu_0 > \nu_Q$, the eigenstates are $\{|\psi_m\rangle\}$, given by

$$|\psi_m\rangle = |m\rangle + \sum_{m' \neq m} C_{mm'} |m'\rangle \quad (4)$$

If the laboratory axes (xyz) and quadrupole principal axes ($x'y'z'$) are related by Euler angles α , β , and γ , the coefficients $C_{mm'}$ are given to first order in ν_Q/ν_0 by

$$\begin{aligned} C_{mm'} = \frac{\nu_Q}{2(m'-m)\nu_0} \{ & -\delta_{m', m+1} [S(S+1) \\ & -m(m+1)]^{\frac{1}{2}} (2m+1) F(\alpha, \beta, \gamma) - \delta_{m', m-1} \\ & \times [S(S+1) - m(m-1)]^{\frac{1}{2}} (2m-1) F^*(\alpha, \beta, \gamma) \\ & + \delta_{m', m+2} \{ [S(S+1) - m(m+1)] [S(S+1) \\ & - (m+1)(m+2)] \}^{\frac{1}{2}} G(\alpha, \beta, \gamma) \\ & + \delta_{m', m-2} \{ [S(S+1) - m(m-1)] [S(S+1) \\ & - (m-1)(m-2)] \}^{\frac{1}{2}} G^*(\alpha, \beta, \gamma) \} \end{aligned} \quad (5a)$$

$$\begin{aligned} F(\alpha, \beta, \gamma) = e^{i\gamma} [& 3 \sin \beta \cos \beta - \eta (\cos 2\alpha \sin \beta \cos \beta \\ & + i \sin 2\alpha \sin \beta)] \end{aligned} \quad (5b)$$

$$\begin{aligned} G(\alpha, \beta, \gamma) = e^{2i\gamma} \left\{ & \frac{3}{2} \sin^2 \beta \right. \\ & \left. + \eta \left[\frac{1}{2} \cos 2\alpha (1 + \cos^2 \beta) + i \sin 2\alpha \cos \beta \right] \right\} \end{aligned} \quad (5c)$$

To second order in ν_Q/ν_0 , the energy E_m of the state $|\psi_m\rangle$ is

$$\begin{aligned} E_m = h\nu_0 \left\{ & -m + \frac{\nu_Q}{2\nu_0} [3m^2 - S(S+1)] (3 \cos^2 \beta - 1) \right. \\ & \left. + \eta \cos 2\alpha \sin^2 \beta + \sum_{m' \neq m} (m' - m) |C_{mm'}|^2 \right\} \end{aligned} \quad (6)$$

The orientation-dependent frequency of the overtone transition in a spin-1 nucleus is then

$$\nu_{1,-1}(\alpha, \beta, \gamma) = 2\nu_0 + \frac{\nu_Q^2}{\nu_0} (|F(\alpha, \beta, \gamma)|^2 + |G(\alpha, \beta, \gamma)|^2) \quad (7)$$

and the orientation-dependent transition moment is

$$\begin{aligned} M_{1,-1}(\alpha, \beta, \gamma) &= \langle \psi_1 | S_x \cos \theta + S_z \sin \theta | \psi_{-1} \rangle \\ &= \frac{\nu_Q}{\nu_0} [\sin \theta F(\alpha, \beta, \gamma) + \cos \theta G(\alpha, \beta, \gamma)] \end{aligned} \quad (8)$$

The nutation frequency (i.e. the inverse of the 2π pulse length) for excitation of the overtone transition is given by $\gamma_S B_1 |M_{1,-1}|/\pi$. The overtone signal amplitude is proportional to $|\rho_{1,-1} M_{1,-1}|$, where $|\rho_{1,-1}|$ is the amplitude of the overtone coherence excited by rf pulses. Thus, equation (8) displays the unusual features of overtone spectroscopy that the nutation frequency depends on the orientation of the quadrupole tensor principal axis system, that overtone transitions can be excited by rf fields applied parallel to the external dc field ($\theta = \pi/2$), and that signals can be detected by rf solenoid coils wound parallel to the dc field. Overtone powder pattern lineshapes in polycrystalline and noncrystalline solids are determined by the orientation-dependent overtone frequency in equation (7) weighted by an orientation-dependent function related to $M_{1,-1}$. The precise details of the weighting function depend on the excitation method. In the linear (i.e. small flip-angle pulse) regime, the weighting function is $|M_{1,-1}|^2$. Equation (8) shows that the weighting function, and hence the observed lineshape, depends on θ .

Since the coefficients $C_{mm'}$ are nonzero only for $|m - m'| = 1$ or 2 , only the first ($\nu \approx 2\nu_0$) and second ($\nu \approx 3\nu_0$) overtone transitions have transition moments proportional to ν_Q/ν_0 , and only the first overtone transition has a transition moment proportional to ν_Q/ν_0 when $\theta = \pi/2$. Higher overtone transitions are weaker, with transition moments proportional to higher powers of ν_Q/ν_0 .

3 EXPERIMENTS

3.1 Detection of ^{14}N Overtone Transitions by CW NMR

Creel et al.⁸ have reported the detection of the ^{14}N spectrum of hexamethylenetetramine by CW NMR methods in fields up to 2.2 T, where $\nu_0 = 6.6$ MHz. The quadrupole coupling frequency $\nu_Q = (e^2qQ)/4h$ is roughly 1.1 MHz in hexamethylenetetramine. Although the fields in these experiments were low by modern standards, they were high enough that the highest frequency ^{14}N signals can be considered to be overtones of the lower frequency signals.

3.2 Indirect Detection of ^{14}N Overtone Transitions

Blinc et al.⁹ measured the ^{14}N NMR spectrum of triglycine sulfate by means of the Hartmann–Hahn double resonance, indirect detection technique.¹⁰ Working in a 0.42 T field, they determined the ^{14}N resonant frequencies by observing proton NMR signals following an adiabatic demagnetization–adiabatic remagnetization cycle, with rf irradiation of the ^{14}N nuclei during a delay period between the demagnetization and remagnetization steps. In such an experiment, the proton NMR signals are destroyed or attenuated whenever the rf frequency is close to a ^{14}N resonance. In the work of Blinc et al., three resonances were observed for a single ^{14}N site, but the dc field was so low that it would be improper to call one resonance an overtone of the others. Essentially the same method was later applied to overtone spectroscopy at considerably higher fields by Tycko and Opella and by Garroway and Miller.¹¹ Related experiments, but involving double quantum rather than overtone excitation, were carried out by Schnur et al.¹² The indirect detection method is a comparatively simple way to locate overtone resonances in organic compounds, with high sensitivity (in favorable cases, on a single transient) but with low resolution. Figure 2 shows double resonance rf pulse sequences for the indirect detection of overtone signals.

3.3 Direct Detection of ^{14}N Overtone Signals Following Double Quantum Excitation

Bloom and LeGros¹ showed that the ^{14}N overtone signals from a single crystal of NaNO_2 , with $\nu_Q = 1.4$ MHz, could be detected directly with adequate sensitivity in a 5.4 T field

Figure 2 Sequences of rf pulses applied to proton (^1H) spins and to an overtone (OT) transition for the indirect detection of overtone transitions in organic solids. (a) Proton dipolar order is created by a two pulse Jeener–Broekaert sequence. A train of OT pulses, with alternating rf phases, destroys part of the dipolar order when the OT carrier frequency is close to a nuclear resonance. Proton NMR signals, proportional to the remaining dipolar order, are detected after the final proton pulse. In a typical application, one scans the OT carrier frequency and looks for a reduction in the proton signal at the OT resonance. (b) Same procedure as (a), but with dipolar order created by adiabatic demagnetization in the rotating frame (ADRF) and proton signals detected after adiabatic remagnetization in the rotating frame (ARRF). A signal enhancement by a factor of 4 over the Jeener–Broekaert method is possible

($\nu_0 = 16.6$ MHz). In the experiments of Bloom and LeGros, rf pulses were not applied at the overtone resonant frequency. Instead, the overtone coherence was excited by the double quantum excitation technique of Vega and Pines,¹³ in which a rf pulse at frequency $\nu_0 + \nu_Q$ ⁽²⁾, with amplitude less than ν_Q/γ_S , is applied for a time about equal to $3\pi\nu_Q/2(\gamma_S B_1)^2$. Thus, signals were detected at twice the frequency of the applied pulses. So far, this method of exciting overtone transitions has been of interest primarily from the standpoint of pure spectroscopy. Excitation near the overtone resonant frequency itself has proven to be a more practical approach.

3.4 Direct Detection and Direct Excitation of ^{14}N Overtone Transitions

Tycko and Opella^{2,3} carried out a series of experiments that demonstrated the feasibility of the direct excitation and direct detection of ^{14}N overtone spectra in single crystal and polycrystalline organic solids. They showed that overtone coherences could be excited both by direct pulsed excitation of the overtone transition and by cross polarization from proton magnetization. They demonstrated the high resolution inherent in overtone spectroscopy when high-power proton decoupling is employed (overtone resonances in single crystals subject to small strains and small degrees of disorder are broadened by second-order rather than first-order quadrupole effects). They showed that quadrupole coupling constants and asymmetry parameters could be determined from overtone lineshapes of polycrystalline samples and that the powder pattern lineshapes depend on the direction of the rf coil used for excitation and detection. They also demonstrated two-dimensional overtone nutation spectroscopy, for measuring overtone nutation frequencies, and two-dimensional overtone separated-local-field spectroscopy, for measuring ^{14}N – ^1H dipole–dipole couplings. Radiofrequency pulse sequences for the acquisition of one-dimensional ^{14}N overtone spectra of organic solids are shown in Figure 3. Examples of one-dimensional ^{14}N overtone spectra are shown in Figures 4 and 5.

Tycko and Opella³ have discussed the comparative sensitivities of ^{14}N overtone spectroscopy and single quantum spectroscopy. Because of the reduced spectral widths and linewidths in typical overtone spectra, overtone spectroscopy has sensitivity at least comparable to that of single quantum spectroscopy despite the weakly allowed nature of overtone transitions.

Tycko and Opella³ have also carried out preliminary experimental investigations of the effects of rapid sample spinning on ^{14}N overtone spectra of polycrystalline solids. They found that spinning about a single axis changed, but did not narrow, the overtone powder pattern lineshape. Takegoshi and Hikichi¹⁴ performed calculations of overtone lineshapes under sample spinning that supported the experimental results. They have also discussed the use of double rotation (DOR) and dynamic angle spinning (DAS) methods as a means of narrowing the second-order quadrupole shift powder patterns observed in ^{14}N overtone spectroscopy.¹⁴ Although this approach to line narrowing has not been demonstrated in experiments, it may turn out to be a valuable one. In principle, either the DOR or the DAS technique, or some suitable variant of these techniques, may allow one to obtain resolved ^{14}N

Figure 3 Pulse sequences for the direct detection of overtone spectra in organic solids. (a) Direct excitation of overtone coherences with a single OT pulse. High-power proton decoupling is applied during the acquisition of the overtone signals. (b) A Jeener–Broekaert sequence is used to create proton dipolar order. Overtone coherences are generated by cross polarization from dipolar order. (c) Adiabatic demagnetization in the rotating frame is used to create proton dipolar order. Overtone coherences are generated by cross polarization from dipolar order. (d) Overtone coherences are generated by cross polarization from transverse proton magnetization, prepared by pulsed spin locking. Pulsed, rather than continuous, spin locking reduces the effective proton rf field, allowing a Hartmann–Hahn match to be achieved despite the relatively weak effective OT rf field (due to the weakly allowed nature of the overtone transitions). (Adapted by permission of the American Institute of Physics from Tycko and Opella, *J. Chem. Phys.*, 1987, **86**, 1761)

overtone NMR lines from chemically inequivalent nitrogen sites in a complex polycrystalline solid (i.e. a polycrystalline peptide or oligonucleotide). The resonant frequencies in such an experiment would be determined by the isotropic parts of the chemical shift and the second-order quadrupole shift. In addition, one expects a small contribution to the overtone lineshapes from a spinning sample due to Berry's phase, as observed in pure NQR spectra of spinning samples.¹⁵ The effects of Berry's phase, which arise because the nuclear spin eigenstates are functions of orientation when the quadrupole coupling is large, are expected to be of the order of $|C_{mm'}|^2 \nu_R$, where ν_R is the sample spinning frequency, which is less than 100 Hz for typical experimental conditions.

Takegoshi and Hikichi¹⁶ have also carried out a rotation study of a single crystal of L-alanine to determine the ^{14}N quadrupole coupling constant and asymmetry parameter in this compound. The observed angular dependences of the overtone frequency and intensity were well described by the expressions derived by perturbation theory.

Ramanathan and Opella¹⁷ have investigated the effects of irradiation of ^{14}N overtone resonances on the ^{13}C NMR spectrum of a single crystal of *N*-acetyl-D,L-valine. The ^{13}C NMR lineshapes at 3.52 T are asymmetric triplets

Figure 4 ^{14}N overtone NMR spectra of a 50 mg single crystal of *N*-acetyl-D,L-valine, obtained at 5.89 T ($2\nu_0 = 36.118$ MHz). The two lines result from the two magnetically inequivalent molecules in the unit cell. All spectra result from the acquisition of 1024 transients. (a) Direct excitation, using the pulse sequence in Figure 3(a). (b) Cross polarization, using the pulse sequence in Figure 3(b). (c) Cross polarization, using the pulse sequence in Figure 3(b), after an arbitrary 10° rotation of the crystal. The change in the overtone resonant frequencies is due to the orientation dependence of the second-order quadrupole shifts. (Adapted by permission of the American Chemical Society from Tycko and Opella, *J. Am. Chem. Soc.*, 1968, **108**, 3531)

for carbon atoms that are coupled to ^{14}N nuclei in this crystal, with asymmetry due to the large ^{14}N quadrupole coupling ($\nu_Q = 0.8$ MHz). Irradiation of the ^{14}N overtone resonances caused the triplet ^{13}C lineshapes to collapse into unresolved doublets. Ramanathan and Opella showed that this 'overtone decoupling' could be carried out selectively, allowing particular ^{14}N overtone resonances to be correlated with particular ^{13}C resonances. Selective overtone decoupling may be useful in the assignment of resonances in single crystal NMR studies.

4 CONCLUSIONS

Overtone spectroscopy is a useful addition to the techniques of solid state NMR. The reduced spectral widths and linewidths of ^{14}N overtone spectra compared with traditional single quantum spectra clearly make overtone spectroscopy the preferred means of applying ^{14}N NMR to the study of many classes of solids. In many cases, overtone spectroscopy is the only practical way to observe ^{14}N NMR signals. At the very least, this allows measurements of spin relaxation rates and approximate quadrupole coupling constants to be performed. Such measurements can probe the chemical, structural, dynamical, and electronic properties of solids.

Extensions of overtone spectroscopy to NMR of nuclei with spins greater than one are possible, but have not yet been

Figure 5 Experimental (a–d) and (e–h) calculated ^{14}N overtone NMR spectra of *N*-acetyl-D,L-valine powder, obtained at 5.89 T (a,b,e,f) and 3.54 T (c,d,g,h) with the pulse sequence in Figure 3(c). The rf solenoid coil used for excitation and detection of overtone signals is perpendicular to the external magnetic field in (a), (c), (e), and (g), and parallel to the external magnetic field in (b), (d), (f), and (h). Each experimental spectrum is the result of approximately 20 000 transients on a 200 mg sample. In the calculations, signal contributions from the various possible molecular orientations are weighted by $-M_{1,-1}$ (see text), and effects of the ^{14}N chemical shift anisotropy are included. (Adapted by permission of the American Institute of Physics from Tycko and Opella, *J. Chem. Phys.*, 1987, **86**, 1761)

investigated in detail. For most quadrupolar nuclei, with non-integer spins, the ‘central transition’ (i.e. the $m = \frac{1}{2} \leftrightarrow m = -\frac{1}{2}$ transition) is already unaffected by first-order quadrupole splittings and is fully allowed. The arguments in favor of overtone spectroscopy are therefore less compelling. Nonetheless, one expects the observation of overtone signals in conjunction with single quantum signals to afford spectral simplification, contribute to the determination of quadrupole coupling parameters, and facilitate the assignment of resonances. The measurement of overtone relaxation rates may also add to the information available from relaxation measurements on the central transition.

1 INTRODUCTION

Phase cycling is a method of canceling out unwanted types of signal from NMR spectra that are generated by a sequence of two or more pulses. The principle is therefore closely related to CYCLOPS,¹ which is used to reduce quadrature images by averaging the response from imperfectly balanced receivers, and is an extension of the use of phase alternation between pulse sequences to reduce the influence of residual transverse magnetization from one FID on the next when time averaging. The essence of the method is to add together a number of FIDs generated by a pulse sequence in which the phases of the radiofrequency pulses are shifted in a specific pattern. The effect of these phase shifts depends on the order of coherence of each component of the magnetization and hence an appropriate phase cycle allows signals that result from a chosen sequence of states to coadd, while all other signals cancel.

I first became aware of the possibilities of the method as a result of a conversation with Dr. S. L. Patt, who brought phase-alternated pulse sequences² to my attention. We had identified nonrefocused magnetization and signals arising from longitudinal relaxation in the two-pulse experiments for COSY and *J* spectra as the source of artifacts in the spectra and were seeking a method of eliminating them. These signals had been given the jocular labels ‘phantoms’ and ‘ghosts’ (now more commonly referred to as axial peaks and antiecho or P-type peaks, respectively), and we developed a four-step phase cycle³ for their removal, which was christened with the name ‘Exorcycle’. Very soon after that, Maudsley and Ernst presented a two-step cycle for selecting only that magnetization which had been transferred between heteronuclei⁴ and, a few months later, Wokaun and Ernst set out the general theory of phase cycling in the context of selecting multiple quantum coherences within pulse sequences.⁵ The ability to select specific signals also laid the foundation for generating ‘pure phase’ two-dimensional spectra by combining signals that are symmetrical about the center of the spectrum in the F_1 dimension, a development which was first announced in an important note added in proof by Bachmann et al.⁶ Thus by the end of 1977 the method had become established to the extent that no new pulse sequence

was published without an associated phase cycle thereafter. Many of the cycles proposed turned out to be fundamentally identical to Exorcycle, prompting a series of articles that set out general principles for designing phase cycles.^{7–9} Most spectroscopists now take the existence of phase cycles for granted, simply having to follow the instruction to set the number of transients for each increment in their experiment to a multiple of some magic number.

An ideal single pulse experiment has no need of phase cycling since the system at equilibrium comprises only populations of the magnetic energy levels, and the FID detected after the pulse is restricted to single quantum coherence by the selection rules. Adding a second, ‘mixing’, pulse of arbitrary flip angle creates two additional routes for magnetization, which may be detected in the FID. First there may be longitudinal magnetization present just before the second pulse, resulting from relaxation and from deviations from a 90° flip angle for the first pulse, and this may be turned into observable magnetization by the mixing pulse. This component is not modulated by the evolution period between the pulses in a two-dimensional experiment and hence appears on the zero frequency axis of the F_1 dimension: the ‘axial’ peaks. Second, part of the transverse magnetization created by the first pulse may be refocused by the mixing pulse. The refocused component is so called because it comes from that part of the magnetization which experiences a 180° phase shift and will go on to form a spin echo. In a two-dimensional spectrum, refocused magnetization appears with negative frequencies in F_1 , whereas the unrefocused part leads to positive frequencies: hence ‘N-type’ and ‘P-type’ peaks. Exorcycle separates these three contributions to the FID by combining the signals from four different experiments in which the relative phase of the mixing pulse is shifted in 90° steps. Essentially all experiments benefit from cancelation of the axial peaks and, in addition, most of the early two-dimensional experiments were designed to retain the N-type peaks and discard the P-type peaks. More recent pulse sequences usually retain both the P-type and N-type peaks but separate them so that they can be recombined to produce signals with pure absorption lineshapes in both dimensions.

2 THEORY

The effect of phase shifting is described most conveniently in terms of the difference in Zeeman quantum number between the stationary states involved in each component of the magnetization. In the eigenbase of the Hamiltonian, each component of magnetization corresponds to a single element of the density matrix and the difference in quantum numbers of the basis functions is known as the ‘order of the coherence’. Thus the population of an energy level represents the coherence of a wavefunction with itself and has order zero. The transverse magnetization generated from isolated spin- $\frac{1}{2}$ nuclei involves both of the wavefunctions, $m_z = +\frac{1}{2}$ and $m_z = -\frac{1}{2}$ and is associated with two elements with order +1 and -1. If, as is usual, a single coil is used for detection, then the choice of the order ascribed to the FID is arbitrary and we shall label it +1, in line with the convention used for the population differences for protons (the operator for the observable being $\hat{I}_+$). The requirement of Exorcycle was therefore to select

Figure 1 A heteronuclear J spectrum (a) haunted by phantoms and (b) obtained with phase cycling. (Reproduced by permission of Academic Press from G. Bodenhausen et al.³)

signals that originated with order 0 before the first pulse of the sequence, evolved with order -1 , and were detected with order $+1$, while canceling all other signals.

Mathematically, the state of any system may be described by a density operator and our viewpoint corresponds to the set of basis functions chosen to represent it, usually eigenfunctions of the spin Hamiltonian. For an isolated spin- $\frac{1}{2}$ nucleus the eigenfunctions of the z component, $\hat{I}_z$, of the spin operator $\hat{\mathbf{I}}$ with eigenvalues $m_z = +\frac{1}{2}$ and $m_z = -\frac{1}{2}$ are labelled $|\alpha\rangle$ and $|\beta\rangle$. The angular momentum operator is $\hbar\hat{\mathbf{I}}$ and the operator for the nuclear magnetic moment $\gamma\hbar\hat{\mathbf{I}}$, so these observables and the voltages that are actually measured are simply proportional to the component of spin. The labels $|\alpha\rangle$ and $|\beta\rangle$ represent solutions of the time-independent Schrödinger equation, but NMR is concerned with coherent radiation and we cannot ignore the time-dependent phase factors of the wavefunctions,

$$i\hbar d|\Psi\rangle/dt = \hat{\mathcal{H}}|\Psi\rangle \quad (1)$$

The time dependence is therefore generated by the operator $\exp(i\gamma B_0 t \hat{I}_z)$ for a magnetic field B_0 applied along the z axis, and we note that the matrix representation of the exponential of an operator in its eigenbase is simply given by the exponentials of the diagonal elements.

The phases are random in a sample at equilibrium so there is no observable transverse magnetization, but let us consider a sample with all of the nuclei in a state $|\psi\rangle = 2^{-1/2}|\alpha\rangle + 2^{-1/2}|\beta\rangle$. This is obviously still an eigenfunction of $\hat{\mathbf{I}}^2$, but it is an eigenfunction of $\hat{I}_x$, since $\hat{I}_x|\psi\rangle = \frac{1}{2}|\psi\rangle$, rather than of $\hat{I}_z$. The z component of the angular momentum of each spin therefore cannot be given simply by an eigenvalue, but is determined by the ensemble average, or expectation value, $\langle\hat{I}_z\rangle = \langle\psi|\hat{I}_z|\psi\rangle = 0$. The expectation value of the

transverse magnetization is no longer zero, but it is certainly time-dependent since

$$\begin{aligned} \langle\hat{I}_x\rangle &= \langle\psi|\exp(-i\gamma B_0 t \hat{I}_z) \hat{I}_x \exp(i\gamma B_0 t \hat{I}_z)|\psi\rangle \\ &= \frac{1}{2} \cos(\gamma B_0 t) \\ \langle\hat{I}_y\rangle &= -\frac{1}{2} \sin(\gamma B_0 t) \end{aligned} \quad (2)$$

so the Larmor frequency emerges from the time-dependent phases of the wavefunctions, and we note in passing that the sense of rotation of the magnetization is negative when the magnetogyric ratio of the nuclei is positive.

This also illustrates how the exponential operators derived from the components of the angular momentum operator generate rotations about the respective axes. Thus, the operator corresponding to measurement along the x' axis in a coordinate frame rotating about the z axis at a frequency ω is obtained from the time-dependent similarity transform

$$\hat{I}'_x = \exp(-i\omega t \hat{I}_z) \hat{I}_x \exp(i\omega t \hat{I}_z) \quad (3)$$

which is effectively what we observe by using a phase-sensitive detector with ω as the reference frequency. The magnetization will therefore appear constant if we measure at a frequency $\omega = -\gamma B_0$. In practice, the use of single-coil detectors means that the sense of rotation is lost and all spectra are plotted as if the frequency were positive, so we shall treat the Larmor frequency as $\Omega = |\gamma B_0|$. However, we can still distinguish signals with absolute frequencies greater or less than that of the reference frequency by means of quadrature detection. The distinction is achieved by splitting the signal into two and detecting it with respect to references that are 90° out of phase, i.e. $\cos(\omega t)$ for detector A and $\sin(\omega t)$ for detector B, and treating each pair of samples as a complex number $S = A + iB$ so that the measuring operator is effectively $\hat{I}_x + i\hat{I}_y = \hat{I}_+$. Simply regarding the signal as $S' = B - iA$ would advance the effective phase of the reference by 90° and hence retard the phase of the resulting spectrum. We shall follow the convention of taking $\hat{I}_+$ to be the operator for magnetization detected in quadrature, regardless of the sign of the magnetogyric ratio, but if we chose to regard the signal as $S'' = A - iB$ then the corresponding observable would be $\hat{I}_-$.

Using explicit matrix representations of the operators of equation (2) in the basis $(|\alpha\rangle, |\beta\rangle)$, the process of calculating the signal generated in quadrature in the rotating frame from our state $|\psi\rangle$ becomes

$$\begin{aligned} S &\propto \begin{pmatrix} \sqrt{\frac{1}{2}} & \sqrt{\frac{1}{2}} \\ 0 & 0 \end{pmatrix} \begin{pmatrix} e^{i(\Omega-\omega)t/2} & 0 \\ 0 & e^{-i(\Omega-\omega)t/2} \end{pmatrix} \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} \\ &\times \begin{pmatrix} e^{-i(\Omega-\omega)t/2} & 0 \\ 0 & e^{i(\Omega-\omega)t/2} \end{pmatrix} \begin{pmatrix} \sqrt{\frac{1}{2}} \\ \sqrt{\frac{1}{2}} \end{pmatrix} \end{aligned} \quad (4)$$

So far we have discussed the time-dependent phase of the wavefunctions and the phase of the signal detected in the rotating frame. This sets the scene for describing the effect of changing the phase of a radiofrequency pulse. The form of pulse operators is described elsewhere and is not essential to a discussion of phase cycling since the designer of the pulse sequence is responsible for ensuring that the proper signals

are generated and the phase cyclist merely has to ensure that the undesirable signals are canceled. The transformation of a system with all of the spins in the $|\alpha\rangle$ state to the one discussed above, in which they are all in the state $2^{-1/2}|\alpha\rangle + 2^{-1/2}|\beta\rangle$, may be achieved with a pulse with a 90° flip angle and the appropriate phase. Note that the phase of the radiofrequency pulses is properly considered as a phase difference between the applied rf field and the reference frequency, since if a pulse with the same frequency as the reference is switched on at some arbitrary point in time, then the absolute phase is also arbitrary. It is the phase of the pulse relative to the reference that is crucial, since the same reference is supplied to the phase-sensitive detector and hence defines the phase of the signals, regardless of the time at which the experiment began.

The ‘phase’ of a pulse will therefore be understood as its phase in a system of coordinates rotating about the axis of the static magnetic field (the rotating frame) at the frequency of the reference that is physically used by the spectrometer. Consider a children’s merry-go-round at a fair: an imaginative stationary observer might believe that the children are driving, for example, toy cars around in circles. An observer standing on the platform would not be surprised to see that those cars had no moving parts. The picture is much simpler in the rotating frame and it is implicit in most descriptions of NMR experiments. To change the phase of his viewpoint in relation to the rotating frame, our observer on the platform could simply walk around the edge. Alternatively, he could step off the platform, have it rotated in the opposite sense, and step back on. The latter approach is certainly more involved, but it makes the effect of phase-shifted pulses more easy to comprehend.

In general we are concerned with complex mixtures of spin states rather than the pure state, $|\psi\rangle = 2^{-1/2}|\alpha\rangle + 2^{-1/2}|\beta\rangle$, used in the example above. It is then convenient to use a density operator and its explicit matrix representation. This contains all of the information necessary to calculate observables in the form of products of the coefficients of wavefunctions averaged across the sample. The density matrix formalism is discussed elsewhere and, as is the case with the explicit form of pulse operators, a detailed understanding is not necessary for our purposes. It is sufficient to note that the transformation from $|\alpha\rangle$ to $|\psi\rangle$ can be expressed in the density matrix formalism as

$$\tilde{\mathbf{P}}^* \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \mathbf{P} = \begin{pmatrix} \frac{1}{2} & \frac{1}{2} \\ \frac{1}{2} & \frac{1}{2} \end{pmatrix} \quad (5)$$

where $\mathbf{P}$ is the matrix representation of the pulse operator. The observable signal is obtained as

$$S \propto \text{Tr} \left(\begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} e^{-i(\Omega-\omega)t/2} & 0 \\ 0 & e^{i(\Omega-\omega)t/2} \end{pmatrix} \begin{pmatrix} \frac{1}{2} & \frac{1}{2} \\ \frac{1}{2} & \frac{1}{2} \end{pmatrix} \right) \times \begin{pmatrix} e^{i(\Omega-\omega)t/2} & 0 \\ 0 & e^{-i(\Omega-\omega)t/2} \end{pmatrix} \quad (6)$$

in which the operator $\hat{I}_+$ has been transformed implicitly into the rotating frame and, since $|\psi\rangle$ was chosen to be a pure state, this expression corresponds simply to a cyclic permutation of the terms in equation (4). Now consider the effect of a pulse which has its phase incremented by 90° ,

$\hat{P}' = \hat{U}^+ \hat{P} \hat{U}$, where $\hat{U} = \exp(\frac{1}{4}i\pi\hat{I}_z)$ provides the similarity transform for a 90° rotation. The result is mathematically identical to applying a negative rotation to the system in its initial state, $\hat{\rho} \rightarrow \hat{U} \hat{\rho} \hat{U}^+$, transforming the system by applying a pulse without any phase shift, and then rotating the system forward again, $\hat{\rho}' \rightarrow \hat{U}^+ \hat{\rho}' \hat{U}$. The effect of shifting the phase of pulses can therefore be understood without reference to the power, duration, frequency, shape, or any other property of the pulse itself. In this simple case, and for all systems at equilibrium, $\hat{\rho} = \hat{U} \hat{\rho} \hat{U}^+$. The only observable change is therefore the forward rotation of the system after the pulse and so the effect of the phase-shifted pulse is to rotate the observed magnetization forward through 90° , as expected.

The result is easily generalized for systems with several magnetic nuclei. The components of the spin operators are given by the direct sum of the components for each of the nuclei present. The eigenfunctions $|\Psi_i\rangle$ are characterized by their total magnetic (Zeeman) quantum number, M_z , and we shall label them accordingly. The magnetic quantum numbers of the individual nuclei are no longer appropriate since they only hold good if the nuclei are weakly coupled, that is if their individual spin operators commute with the complete spin Hamiltonian. A straightforward expansion of the operator for rotation about the z axis then shows that applying a rotation through an angle θ to the system has the effect of changing the phase of elements of the density matrix according to the prescription

$$\rho_{rs} \rightarrow \exp[i\theta(s-r)] \rho_{rs} \quad (7)$$

in which we note that the imaginary part of ρ_{sr} changes in the opposite sense to that of ρ_{rs} , maintaining the Hermitian property of the density matrix. The difference in M_z between the basis functions, $s-r$, is known as the order of coherence of the matrix element ρ_{rs} . This follows the opposite sign convention to that introduced by Wokaun and Ernst⁵ for the ‘transition order’ and agrees with that of Bain,⁸ who called it the ‘coherence level’.

In terms of the individual density matrix elements, the example above which describes a pulse with a 90° phase shift applied to a system of isolated spin- $\frac{1}{2}$ nuclei involved first the negative rotation

$$\rho_{\alpha\alpha} \rightarrow \exp[-\frac{1}{2}i\pi(\frac{1}{2} - \frac{1}{2})] \rho_{\alpha\alpha} = \rho_{\alpha\alpha} \quad (8)$$

followed by a pulse with no phase shift, and then obtaining the signal $S \propto \rho_{\beta\alpha}$ after restoring the system to its original reference coordinates by means of the positive rotation

$$\rho_{\beta\alpha} \rightarrow \exp[\frac{1}{2}i\pi(\frac{1}{2} - (-\frac{1}{2}))] \rho_{\beta\alpha} = i\rho_{\beta\alpha} \quad (9)$$

so that the signal acquires the expected 90° phase shift.

Although the theory of phase cycling does not require an understanding of free precession and relaxation, it is important to note that these do not affect the order of coherence, at least not in a coherent fashion. Obviously, any state will return to equilibrium, order zero, if it is left for long enough, but this is the result of random changes in the spin states of individual nuclei so that all phase coherence is lost. A change in the order of coherence requires that the nuclei all experience the same perturbation simultaneously, i.e. the

perturbation itself must be coherent. This is taken for granted in radiofrequency spectroscopy since the technology required to generate monochromatic radiation with phase coherence throughout large samples has been available for many years. A change in the order of coherence, that is a change in spin state which occurs with phase coherence across the sample, therefore requires an applied coherent radiofrequency field, or pulse. Radiofrequency pulses transfer magnetization between elements of the density matrix, $D_{pqrs}\rho_{pq} \rightarrow \rho_{rs}$, where D_{pqrs} is a coefficient for the transfer of coherence which depends on the exact form of the pulse. These coefficients can remain part of a black box for our purposes, and hence, by extension of equations (8) and (9), a phase-shifted pulse generates

$$D_{pqrs}^\theta \rho_{pq} \rightarrow \exp[i\theta(p - q + s - r)] \rho_{rs} \quad (10)$$

The final step of quadrature detection produces signal exclusively from elements for which $s - r = +1$, and so we are ready to analyze any phase cycle.

3 EXORCYCLE

Exorcycle was developed to select N-type peaks in a two-pulse experiment so the mixing pulse is required to generate a 180° phase shift, or inversion, of the magnetization. Since we detect ρ_{rs} , where $s - r = +1$, we are only interested in the part of the magnetization present before the pulse, ρ_{pq} , for which $q - p = -1$. That magnetization should be generated from a system at equilibrium, for which only the diagonal elements ρ_{kk} are nonzero. The signals are therefore required to follow the route $0:-1:+1$, where pulses are indicated by colons and the numbers specify the orders of coherence between pulses. If the initial pulse and the mixing pulse have relative phases θ and ϕ , which were restricted to multiples of $\pi/2$ when Exorcycle was developed, then the initial pulse gives

$$D_{kpq}^\theta \rho_{kk} \rightarrow \exp[i\theta(k - k + q - p)] \rho_{pq} \quad (11)$$

and the mixing pulse gives

$$D_{pqrs}^\phi \rho_{pq} \rightarrow \exp[i\phi(p - q + s - r)] \rho_{rs} \quad (12)$$

Overall, the phase shifts cause the desired signal from the route $0:-1:+1$ to change by a factor $\exp[i(2\phi - \theta)]$. This phase shift must be constant if the signal is to add coherently with a constant receiver phase. The phase of the signals is arbitrary so long as it is constant for all steps of the phase cycle, but it is convenient to let that constant phase be zero, i.e. $2\phi - \theta = 2n\pi$. If the mixing pulse is incremented in 90° steps, $0, \pi/2, \pi, 3\pi/2$, in separate experiments then the initial pulse must have the phases $0, \pi, 0, \pi$. The undesirable axial peaks arise from the route $0:0:+1$, and the P-type peaks from $0:+1:+1$, and Table 1 gives the phase factors for each type of signal in the four steps of the cycle.

The sum of the four experiments clearly cancels both of the undesirable signals, but the cancelation will be imperfect if any instability alters the characteristics of the spectrometer. Since axial peaks are often the most intense, it may be preferable to take the transients in the order 1, 3, 2, 4, so that any change in

Table 1 Phase Factors for Four-Step Cycle

	θ	ϕ	N-type $\exp[i(2\phi - \theta)]$	P-type $\exp(i\theta)$	Axial $\exp(i\phi)$
1.	0	0	+1	+1	+1
2.	π	$\pi/2$	+1	-1	+i
3.	0	π	+1	+1	-1
4.	π	$3\pi/2$	+1	-1	-i

the spectrometer that occurs between FIDs which cancel the axial contribution when co-added is as small as possible.

If the experiment is of the type in which the P-type and N-type signals are of equal intensity, then the combinations of signals $1 + 2 + 3 + 4$ and $1 - 2 + 3 - 4$ may be stored separately for processing into pure absorption lineshapes, thereby enhancing both sensitivity and resolution.

More recent spectrometers allow phase shifts other than 90° , and the cycle may be reduced to three steps if 120° shifts are available,⁹ though this may be less satisfactory since precise 120° shifts are more difficult to obtain and the cycle is not easily adapted to produce pure absorption lineshapes. The phase factors for the three-step cycle are shown in Table 2

Although these explicit phase cycles are chosen to give a zero phase shift for the desired signal, it should be noted that arbitrary constant shifts may be added to the initial pulse, and to the mixing pulse, and, since it is all relative, to the reference used in the receiver. That would only alter the phase of the desired signal in the eventual spectrum, which normally requires some correction in any case, and would not affect the cancelation of the other signals. This is true of all phase cycles, so that particular experiments may appear with phase cycles which are dressed up differently but are in principle identical.

The addition of CYCLOPS to suppress the 'quadrature images' which are produced by unbalanced detectors involves shifting the effective phase of the reference frequency by exchanging the signals from the two detectors, $B - iA = \exp(-i\pi/2)(A + iB)$, and hence requires 90° to be added to the phase of both pulses in each step of the cycle. The operator for measuring the signal is intended to be $\hat{I}_+$ but this is distorted to give $\hat{I}_+ + \delta\hat{I}_-$ if the detectors are unbalanced. This admits detection of magnetization of order -1 , which has an apparently negative Larmor frequency, $\Omega_{-1} = -\Omega_{+1}$, and so leads to the peaks known as quadrature images. As it stands, Exorcycle would not distinguish the desired route $0:-1:+1$ from the mirror image, $0:+1:-1$. The 90° phase shift applied to both pulses introduces a 90° phase shift of all signals arising from routes of the type $0 \dots +1$, and -90° for signals arising from routes of the type $0 \dots -1$. Advancing the effective receiver phase retards the apparent signal phase and so restores the phase of the $0 \dots +1$ signals to zero, but it leaves the $0 \dots -1$ signals shifted by 180° so that they cancel out. This refinement may not be essential since a

Table 2 Phase Factors for Three-Step Cycle

	θ	ϕ	N-type $\exp[i(2\phi - \theta)]$	P-type $\exp(i\theta)$	Axial $\exp(i\phi)$
1.	0	0	+1	+1	+1
2.	$2\pi/3$	$4\pi/3$	+1	$-\frac{1}{2} + i(3/4)^{1/2}$	$-\frac{1}{2} - i(3/4)^{1/2}$
3.	$4\pi/3$	$2\pi/3$	+1	$-\frac{1}{2} - i(3/4)^{1/2}$	$-\frac{1}{2} + i(3/4)^{1/2}$

properly adjusted receiver should produce images that are no more than a few percent of the ‘true’ signal.

4 MULTIPLE QUANTUM SELECTION

The extension to multiple quantum experiments is straightforward if the notion of a pulse is broadened slightly. Generating multiple quantum coherence requires at least two pulses which are separated by a fixed delay, or an extended composite pulse. These complex pulses are black boxes which need not be opened if the phase shift is understood to apply to all segments of the sequence. We might wish to select refocused triple quantum magnetization according to the route $0:-3:+1$. Let the whole of the initial pulse or pulse sequence be given a phase shift θ , and the mixing pulse (or ‘read’ pulse) a shift of ϕ . The desired signal undergoes a phase shift of $\exp[i(4\phi - 3\theta)]$ and so the ability to shift the phase in steps of $\pi/6$ is convenient, allowing steps of 120° for θ and 90° for ϕ . The sum of 12 transients in which ϕ cycles through $0^\circ, 90^\circ, 180^\circ$, and 270° with θ fixed at 0° for the first group of four, 120° for the second, and 240° for the third, will select only magnetization which has evolved with an order of coherence $-3 \pm 12n$. The coherence transfer coefficients are unlikely to allow significant magnetization of the order of $+9$ or higher to be present, so the route is effectively unique. Similarly, subtracting alternate signals in this cycle will select the P-type signals from the route $0:+3:+1$, which have the phase factors $\exp[i(-2\phi + 3\theta)]$.

A simple alternative description of the effect of phase shifting pulses is now apparent: if a pulse changes the order of a coherence from $Q = q - p$ to $S = s - r$ then shifting the phase of that pulse by an angle θ will change the phase of the signal through an angle $\theta(S - Q)$. Since the ‘pulse’ may involve any number of segments, adding 90° to both θ and ϕ in the example above, which involves magnetization beginning with order 0 and finishing with order $+1$ as usual, will shift the phase of the signal by 90° , and switching the output from the quadrature detectors from $A + iB$ to $B - iA$ will achieve the improvements of CYCLOPS as before.

5 HETERONUCLEAR EXPERIMENTS AND SELECTIVE PULSES

Important simplifications arise whenever the spin Hamiltonian factorizes, that is whenever the operator $\hat{F}_z^S$ for some subgroup (S) comprising one or more nuclei commutes with the complete Hamiltonian. This is true whenever spins are weakly coupled, which is often the case for a homonuclear system and is almost always the case for nuclei of different isotopes. It is then possible to classify each spin wavefunction according to the magnetic quantum numbers of the subgroups, as well as for the total, and to consider pulses which act selectively on one of the subgroups. Consider two strongly coupled protons forming an AB system: the total magnetic quantum number may take the values $-1, 0, +1$, but quantum numbers of the individual nuclei are not meaningful for the mixed wavefunctions and, for the same reason, it is not possible to produce a pulse that will affect one nucleus and not the other. If the nuclei are weakly coupled, as in an AX system, then

the individual nuclei have good quantum numbers (the wavefunctions are simply products of the eigenfunctions of the two nuclei), and it is straightforward to perturb the transitions of one nucleus without affecting the other. Whenever this ‘X-approximation’ is applicable, the overall order of coherence is given by the sum of the orders of coherence of each of the subgroups which interact weakly with each other, and radiofrequency pulses may be applied selectively to the subgroups of nuclei.

All pulses are in reality selective pulses since, for example, a pulse applied at the proton frequency will have a negligible effect on ^{13}C transitions. Breaking the overall order down into the sum of the orders of the subgroups, $p_{\text{tot}} = \sum p_k$, is convenient since a pulse which affects subgroup S can only alter the order with respect to this group. Thus the discussion of Exorcycle or the selection of multiple quantum states in a system of protons, labelled I , would not be altered by the presence of heteronuclear spins, labelled S , so long as the pulses are selective for protons and the order of coherence is understood to be the proton order p_I , where $p_{\text{tot}} = p_I + p_S$. Since the orders are integral no matter what spins the individual nuclei have, and the detection of signals requires that $p_{\text{tot}} = +1$, then to observe a proton signal requires that p_I equals $+1$ and any heteronuclei must therefore have the same order as at equilibrium, $p_S = 0$, so they can be neglected.

The value of splitting up the overall order becomes apparent in experiments with pulses applied separately to two or more subgroups. Consider a heteronuclear experiment that concludes with the detection of a signal at the proton frequency, $p_I = +1$, $p_S = 0$, after a variety of pulses have been applied to each group of nuclei: since the experiment begins and ends with $p_S = 0$, the result must be independent of any phase shift that is applied to all of the pulses on the heteronuclei, and so the transmitter at the heteronuclear frequency does not need to be phase-locked with the proton transmitter.

Heteronuclear J spectra provide the simplest example. The nuclei to be observed, commonly ^{13}C , follow the route $0:-1:+1$ which is selected by Exorcycle. The heteronuclei, usually protons in this case, are unaffected at the time of the initial pulse applied to the ^{13}C nuclei, indicated by a point, and are inverted by a pulse which is simultaneous with the ^{13}C mixing pulse, indicated by a colon, and so the protons follow the route $0:0:0$. The result is clearly independent of the phase of the pulse that inverts the heteronuclei, but this means that phase cycling is incapable of eliminating magnetization in which the heteronuclei are not inverted.

Now consider the heteronuclear shift correlation experiment in which the S spins are excited, the magnetization evolves, and is then transferred to the I spins by a mixing pulse that involves separate pulses at frequencies ω_I and ω_S , and is finally detected with respect to the reference ω_I . P-type peaks arise from magnetization that has p_S following the route $0:+1:0$, while p_I follows $0:0:+1$. Once again, it is clear that a phase shift applied to both of the I pulses will not affect the signal since the magnetization begins and ends with $p_S = 0$, and so the relative phase of the transmitters of ω_I and ω_S at the beginning of the experiment is irrelevant. If these pulses are obtained simply by switching the amplifier on and off with a continuous input at the frequency ω_S then the phase of the second pulse relative to the reference at frequency ω_I will be shifted by an additional amount $t_1(\omega_S - \omega_I)$, where t_1 is the time delay between the two pulses. At first sight this would

appear to shift the phase of the signal by $t_1(\omega_S - \omega_I)$, and since t_1 is incremented during a two-dimensional experiment, this would introduce a frequency shift of $-(\omega_S - \omega_I)$ into the F_1 dimension. However, the actual frequency for evolution of the S spins during t_1 is given by $(\Omega_S - \omega_I)$ in the frame rotating at the reference frequency and so the signals appear at the F_1 frequency $(\Omega_S - \omega_S)$. This is exactly the same frequency that would be obtained in a normal one-dimensional experiment for observing the S spins directly with a reference at ω_S . So it turns out that considering the phase of the S spin pulses with respect to the reference at ω_I is an unnecessary complication.

A more straightforward picture emerges in a frame that rotates both at the frequency ω_I and at ω_S . This may seem complex, but, returning to the fairground, think of a more sophisticated merry-go-round complete with riding horses. Our stationary observer might believe that there is a herd of horses leaping and running in a circle, but an observer riding on the platform would see wooden horses fixed on poles that are simply moving up and down. To admire the artwork on the horses, the observer would be better placed sitting astride one of them. The transformation of the wavefunctions of an isolated spin into the rotating frame was accomplished with the operator $\hat{U} = \exp(i\omega t \hat{F}_z)$ and the corresponding operator for a multispin system is $\hat{U} = \exp(i\omega t \hat{F}_z)$. Now $\hat{F}_z = \hat{F}_z^I + \hat{F}_z^S$, and these operators must commute since they affect different groups of spins. Therefore

$$\begin{aligned}\hat{U} &= \exp(i\omega t \hat{F}_z^I) \exp(i\omega t \hat{F}_z^S) \\ &= \exp(i\omega t \hat{F}_z^S) \exp(i\omega t \hat{F}_z^I)\end{aligned}\quad (13)$$

and there is no reason why the frequencies of rotation for the two groups of spins should not be different. In fact most descriptions of heteronuclear experiments make implicit use of the *doubly* rotating frame generated with $\hat{U} = \exp(i\omega_I t \hat{F}_z^I) \exp(i\omega_S t \hat{F}_z^S)$. It is therefore convenient to extend the definition of the phase of a pulse whenever the X approximation applies such that the phase of any pulse at frequency ω_Q is understood to be relative to a reference frequency that also has frequency ω_Q .

In the heteronuclear shift correlation experiment described above, selection of the route $0:\pm 1:0$ for the S spins simply requires that the second pulse at frequency ω_S has an equal and opposite phase shift to the first, while the I spins follow the route $0:0:+1$. CYCLOPS compensation may be achieved by adding 90° phase shifts to the single pulse at frequency ω_I and switching the output of the detectors. This is suitable if the spectrum is to be processed with pure absorption lineshapes, otherwise it is preferable to select the N-type peaks that have the route $0:-1:0$ for p_S . Not surprisingly, the phase cycle for this is none other than Exorcycle in which the phases for pulses at frequency ω_I are defined with respect to the reference at ω_I and those of pulses at ω_S are defined with respect to the reference at ω_S .

Heteronuclear multiple quantum experiments are only slightly more complex. Selection of a refocused signal that has evolved as heteronuclear double quantum magnetization¹⁰ requires the observed nucleus to follow the route for p_I $0:-1:+1$, which can be selected by applying Exorcycle to the pulses with frequency ω_I , and the heteronuclei follow the route for p_S $0:-1:0$. The pulses in this case must not be simultaneous, otherwise the coefficients for transfer to the

double quantum state, $p_{\text{tot}} = -1 - 1$, will be zero, but this is irrelevant to the design of a phase cycle. The relative phase of the transmitter for the heteronuclear S spins is again unimportant since p_S is unchanged by the complete sequence, beginning and ending at zero. Equal and opposite phase shifts applied to the two heteronuclear pulses will leave the signal phase unaltered, but will not distinguish magnetization that has evolved with $p_S = +1$ or -1 . If an additional 90° phase shift is added to the first ω_S pulse, which changes p_S by ± 1 , then signals from these two routes will be shifted by 90° in opposite directions: it does not matter that the pulse generates so-called heteronuclear multiple quantum magnetization since the order of coherence of the I spins is not affected. Adding 90° to all of the pulses at ω_I and summing will therefore select $p_S = +1$ and cancel $p_S = -1$.

6 PURE ABSORPTION LINESHAPES

The principles outlined so far have concerned the selection of signals that arise from a single, unique, route of coherence transfer. Such signals are phase modulated in two (or more)-dimensional experiments and hence give rise to ‘phase twisted’ lineshapes in the final spectrum, that is lineshapes that are an admixture of double absorption and double dispersion. The absorption lineshape is symmetric about the line frequency and the dispersion is antisymmetric, so a pure absorption lineshape could be obtained by taking the mirror image of a line about its center and adding it to the original. This is totally impracticable in complicated spectra. Refocused and nonrefocused signals, the N-type and P-type peaks that evolved with equal and opposite orders of coherence, automatically appear at frequencies which are mirror images about $F_1 = 0$, and so taking the mirror image of one group and adding it to the other will produce pure absorption lineshapes throughout the spectrum *so long as* the intensities are equal in the two groups. The principles of separating signals that have evolved with order $\pm n$ were noted in the description of Exorcycle, and it can be seen that it costs nothing in spectrometer time to keep both signals, but brings the advantage of a $\sqrt{2}$ improvement in sensitivity when they are coadded.

Reversal and addition of these signals is straightforward once they have been separated. This recombination may be achieved by a number of fundamentally equivalent methods of data handling that need not concern us here. There are two common methods for the separation of the mirror image signals: the use of separate storage areas for the two signals, and frequency shifting. As discussed in Section 3, most phase cycles that can be used to select a route $0:-n:+1$ can also be used to select the route $0:+n:+1$ if half of the signals are subtracted instead of added. For example, in the table of phase shifts used in Exorcycle, the simple sum of the four signals leaves only N-type peaks, and the combination of signals $1 - 2 + 3 - 4$ leaves only P-type peaks. These two combinations may be stored and processed separately.

Alternatively, P-type and N-type signals may be selected simultaneously by using only steps 1 and 3 of the cycle, in which case they must be separated by being shifted into different regions of the spectrum. The reference frequency is usually placed in the center of the spectrum and the sampling rate and size of increments in the evolution time are adjusted such that the spectral widths are just large enough to include

all of the signals. In that case the P-type and N-type signals occupy the same spectral region and cannot be separated. Separation into different spectral regions therefore requires that the spectral width be doubled and that P-type and N-type signals each be shifted by half of the original spectral width, in opposite directions. This is easily achieved in the F_1 dimension of a two-dimensional experiment since the evolving signals are not observed in real time, successive samples being taken from different increments in the experiment. If the initial pulse has its phase shifted by 90° for each increment in the evolution time, then the P-type signals, which have order $+1$ during the evolution period, will have their phases advanced by 90° in each increment, while the N-type signals, which evolve with order -1 , have their phases retarded. This corresponds to an apparent increase in the F_1 frequencies of the P-type peaks by one-quarter of the new, doubled, spectral width and an apparent decrease in the F_1 frequencies of the N-type peaks by the same amount. Hence the two groups of signals have been shifted far enough apart to remove the overlap and the two halves of the spectrum can be combined to give pure absorption lineshapes. The same principle, sometimes called 'time proportional phase incrementation' or 'Redfield quadrature', may be applied to signals that evolve with orders $\pm n$ by applying proportionately smaller phase increments to all of the pulses in the preparation sequence.

These procedures appear to be very different, but the results are virtually identical: frequency separation requires a phase cycle which has only half as many steps as that needed to distinguish P-type and N-type peaks in order to store them separately, but doubling the spectral width in F_1 means that twice as many increments are needed to provide the same digital resolution. The two methods therefore require the same length of time and the same amount of data storage; only folded signals and artifacts that have escaped the phase cycle could tell the difference.

It is up to the designer of the pulse sequence to ensure that the coherence transfer coefficients are identical for the mirror image routes, but there are a few aspects of the requirement for equal intensities that relate to the theory of phase cycling. Preparation of the system is generally symmetric since the orders $\pm n$ are obtained from order zero at equilibrium: the breakdown of symmetry is associated with detecting order $+1$ and rejecting -1 with phase-sensitive detectors in quadrature, which is reinforced by CYCLOPS. The NOESY experiment, for example, involves selecting orders $0:\pm 1:0:+1$, where the second period with zero order is the fixed mixing time during which the longitudinal relaxation cross relaxes or exchanges chemically. Evolution with order $+1$ or -1 is therefore treated equally, regardless of the flip angle of the pulses, and so it is straightforward to obtain pure absorption lineshapes. The basic COSY experiment, however, requires a mixing pulse of exactly 90° flip angle to produce symmetric P- and N-type peaks. This requirement does not apply to heteronuclear shift correlation since the selective pulses process the coherence of the heteronuclei symmetrically through the orders $0:\pm 1:0$, while the observed nuclei follow the route $0:0:+1$.

7 OPTIMUM ORDERING WITHIN CYCLES

This discussion of the principles of phase cycling has taken a constant receiver phase as its basis in order to present the

minimum cycle necessary to select the chosen route for the signals. Generally, a sequence that involves x separate pulses with phase shifts in multiples of π/y will allow $2xy$ different combinations, each of which will present the desired signal with different phases, but these signals may all be coadded if the receiver phase is shifted appropriately. Exorcycle plus CYCLOPS involves two pulses and phase shifts of $\pi/2$ so that the maximum cycle has a manageable 16 steps. The example of triple quantum magnetization has a cycle which expands to 48 steps with the inclusion of CYCLOPS. The basic three-pulse NOESY experiment would require 64 steps if $\pi/2$ phase shifts are used, and so on. In an experiment that required 10 000 transients to obtain adequate sensitivity and only 1000 increments to provide sufficient digital resolution, such complete cycles would be acceptable, but if 1000 transients were sufficient for sensitivity then using a phase cycle would multiply the length of the experiment unnecessarily. It is therefore convenient to take the steps of each complete phase cycle in an order that cancels the most disturbing artifacts in the shortest loops and then goes on to cancel lesser irritants if time allows. This is also desirable in view of spectrometer instability and, as noted above, axial peaks may be canceled in just two steps. The most intrusive artifact of all is the signal from protons without heteronuclear couplings in 'reverse-mode' correlation experiments involving heteronuclei of low abundance, but this may also be dealt with in two steps along with the axial peaks. If the time available for the experiment allows only a single step for each increment, as may be the case in three- or four-dimensional experiments, then there is no room at all for phase cycling, and the use of field gradient pulses may be the only alternative. This is a crude method insofar as unwanted magnetization is only attenuated, never eliminated, and it is impossible to retain P-type peaks together with N-type peaks for producing pure absorption lineshapes and enhancing sensitivity. The use of field gradients instead of phase cycles, which was first outlined in 1977⁵ and has been reinvented several times since then, has led to important technological developments. Excellent results can be obtained when the spectrometer stability is poor or the system has insufficient time to return to equilibrium and cancellation is therefore imperfect; these techniques are described elsewhere.

The question of ordering phase cycles is complicated to some extent by the fact that systems are never at equilibrium at the beginning of each pulse sequence since there may also be some coherence persisting after the previous FID. Higher order coherence decays rapidly and even single quantum coherence may be attenuated by field gradient pulses during the relaxation period, but there may be persistent unobservable zero quantum coherence or longitudinal J ordered states (also of order zero) left over from the previous pulse sequence. Although the amplitude of multiple quantum coherence after a single pulse is applied to a system at equilibrium is negligible, residual zero-order coherence may be converted into higher order coherence and the Exorcycle sequence will allow signals from the route $0:+3:+1$ to add coherently. However, each step of the phase cycle increments the phase of residual zero quantum magnetization by 90° so that if the following sequence turns it into observable signal with its phase unchanged it will cancel over a four-step cycle.

A more insidious problem arises when the residual coherence is presented with a phase shift that is reversed by the next

pulse sequence. The routes $0:\pm 1:0$ leave a residual longitudinal magnetization which oscillates through the basic Exorcycle sequence, resulting in a cyclic deviation from a notional 'steady state', which replaces the true equilibrium at the start of each pulse sequence. The ordering described above causes P-type peaks to be canceled by alternate transients, effectively modulating their intensity with respect to the transient number at twice the rate of the residual longitudinal magnetization, and so its effects are canceled. However, if the sequence is reordered to provide axial peak cancellation on alternate scans then the modulation of the residue and of the P-type peaks are matched and the cancellation will be imperfect. Unfortunately, the relative magnitudes of different types of artifact in a particular type of spectrum depend upon the recycle time, the nature of the sample, and the state of the spectrometer, and so the optimum ordering for the steps of each phase cycle is a matter of trial and error.¹¹

Finally, it must be stressed that phase cycling is essentially a difference method and so depends critically on the stability of the spectrometer and the accuracy of the phase shifts it provides. The stability of the phase of the radiofrequencies is of particular concern. When instrument designers are seeking to improve this, they must also bear in mind that essentially all useful phase shifts are simple *rational* numbers of circles: a phase which must be set in multiples of 1.1° , for example, cannot provide accurate shifts of π/n . For these reasons, there can be no completely general prescription for optimum ordering within cycles and there may even be differences between spectrometers of the same model.

1 INTRODUCTION

The use of the spatial variation of the static magnetic field B_0 is almost as old as NMR. The very first experiment, namely the Hahn spin echo experiment, did rely on the condition that, if B_0 is not perfectly homogeneous across the sample (and can be made purposely inhomogeneous), it produces a dephasing that can be refocused by a proper spin manipulation. As everyone knows, this property has led to numerous applications, ranging from the measurement of translational diffusion coefficients to NMR imaging, including purely spectroscopic applications such as the selection of coherence pathways. Less attention has been paid to the possibility of taking advantage of the spatial variation of the other magnetic field involved in any NMR experiment, namely the radiofrequency field B_1 , which is necessary for inducing transitions or, in a more general way, for manipulating nuclear magnetization and especially taking it away from its equilibrium position or creating nonequilibrium spin orders.

The incentive for substituting B_0 gradients by B_1 gradients originates from the recognition that

1. B_1 gradient pulses involve negligibly small rise and fall times because they are created via tuned circuits;
2. they do not entail any eddy currents as do B_0 gradients;
3. they do not perturb the frequency/field lock channel;
4. the relevant instrumentation is relatively simple compared with that required by B_0 gradients.

However, there do exist some drawbacks related to

1. the difficulties of generating strong B_1 gradients;
2. creating independent B_1 gradients along the three spatial dimensions.

Nevertheless, the first suggestion of using B_1 gradients (combined with B_0 gradients) for performing NMR imaging, dates from the end of the 1970s, and was dubbed rotating frame zeugmatography.¹ The exploitation of B_1 gradients in relation with surface coil methodology^{2,3} and spectroscopic imaging⁴ was developed during the 1980s. However, these methods aimed at one-dimensional spatial selection, and do not rely necessarily on *uniform* gradients. On the purely spectroscopic side, B_1 gradients (or rather the inevitable inhomogeneity of the B_1 field delivered by the transmitter coil

of a high-resolution NMR spectrometer) were used during the same period for purging purposes⁵ or for selecting specific coherences.⁶

B_1 gradient pulses will be discussed here, with the emphasis on their potential for

1. the measurement of self-diffusion coefficients and the study of flow;
2. two-dimensional imaging;
3. the selection of coherence pathways.

These capabilities are based on the usual defocusing and refocusing properties of gradients combined with the fact that a B_1 gradient acts on nutation (rotation about the B_1 axis in the rotating frame) and not on precession as does a B_0 gradient. Since the B_1 amplitude is several orders of magnitude smaller than the B_0 amplitude, B_1 gradients do not suffer from some problems encountered with B_0 gradients that are directly related to factors affecting the resonance frequency, namely residual B_0 inhomogeneity, magnetic susceptibility variations across the sample, and various heterogeneities that may contribute to lowering the effective transverse relaxation time T_2^* . In fact, the effective relaxation rate during the application of a B_1 gradient pulse is given by⁷

$$\frac{1}{T_{1,2}} = \frac{1}{2} \left(\frac{1}{T_1} + \frac{1}{T_2} \right) \quad (1)$$

In this expression, T_2^* is not involved (for the reasons mentioned above), and, even in unfavorable situations where T_2 is short and much smaller than T_1 , $T_{1,2}$ is seen to be twice as large as T_2 . This feature may be appreciable, especially in the context of imaging experiments. The mechanism by which a B_1 gradient pulse (of duration τ) acts on magnetization can be understood through the nutation angle, which depends on the location of the considered magnetization along the gradient axis X (in the following, the laboratory frame axes will be denoted by capital letters X , Y , and Z , where the Z axis coincides with the direction of B_0):

$$\theta(X) = 2\pi kX \quad (2)$$

where the usual k variable has been introduced:

$$k = \frac{\gamma g_1 \tau}{2\pi} \quad (3)$$

g_1 being the gradient strength. For a gradient pulse of sufficient duration and a homogeneous sample, the following averages (over the whole sample) hold:

$$\left. \begin{aligned} \langle \sin \theta \rangle &= \langle \cos \theta \rangle = \langle \sin 2\theta \rangle = \langle \cos 2\theta \rangle = 0 \\ \langle \sin^2 \theta \rangle &= \langle \cos^2 \theta \rangle = \frac{1}{2} \end{aligned} \right\} \quad (4)$$

It must be borne in mind, however, that the spatial encoding represented by equation (2), as well as the averages given above are reversible processes: refocusing can be made to occur by applying the same gradient pulse but with the radiofrequency field shifted in phase by 180° .

It should finally be mentioned that experiments based on B_1 gradients can be carried out with only slight modifications of a standard high-resolution NMR spectrometer. The basic experimental set-up is shown in Figure 1;^{8,9} it is essentially a high-resolution probe to which a single turn coil has been

Figure 1 The design of a probe adapted to a vertical cryomagnet. The saddle coil is used for detection purpose and/or for generating homogeneous rf pulses. The B_1 gradient is delivered by the simple single turn coil, appropriately located in order to make it uniform across the sample (object) under investigation.⁸

added for radiofrequency field gradient generation. These two coils can be fed by two different transmitters whose relative phases can be adjusted so that they operate in the *same* rotating frame.

2 TRANSLATIONAL DIFFUSION AND FLOW VELOCITY MEASURED BY MEANS OF RADIOFREQUENCY GRADIENTS

A straightforward sequence⁹ devised for measuring self-diffusion coefficients by means of B_1 gradients is a sort of replica, although somewhat simpler, of the well-known PFGSE using B_0 gradients.¹⁰ It is sketched in Figure 2. The first B_1 gradient pulse produces a dephasing, depending on the location of the considered elementary magnetization [see equation (2)] which, owing to the central π pulse, would be entirely refocused along the z axis by the second gradient pulse. The last $\pi/2$ pulse would thus probe the whole longitudinal nuclear magnetization (possibly affected by relaxation). However, because molecules translate during the interval Δ , the nutation induced by the second gradient pulse is different from that produced by the first gradient pulse, and longitudinal magnetization is not entirely refocused. Along the same lines as for the PFGSE experiment, it can be shown that the longitudinal magnetization is attenuated by a factor $\exp(-\gamma^2 g_1^2 \delta^2 D \Delta)$, as long as $\Delta \gg \delta$ and provided that

relaxation during Δ has been disregarded. In practice, Δ is maintained at a fixed value and the experiment is repeated for different values of δ ; attenuation due to relaxation phenomena is therefore irrelevant, since they affect all experiments in the same way. At the outset, the magnetization measured by the final $\pi/2$ read pulse is plotted as a function of δ^2 , yielding the diffusion coefficient D . In alternative sequences,^{11,12} the central homogeneous π pulse is dropped; refocusing relies on the average $\langle \cos^2 \theta \rangle = \frac{1}{2}$ [see equation (4)], entailing a reduction of signal intensity by a factor of $\frac{1}{2}$. The simple two-step phase cycle indicated in Figure 3 removes all contributions of transverse magnetization, which would otherwise lead to the formation of stimulated echoes. An interesting feature of this sequence comes from the fact that a homogeneous $\pi/2$ read pulse is not strictly necessary, and can be delivered by the gradient coil. The corresponding flip angle is therefore not exactly the same in all parts of the sample, causing no problem, since one is interested in evaluating the diffusion coefficient for the whole sample (by varying δ).

Finally, it should be mentioned that these sequences can also be used for studying coherent motions. As a simple example, one may consider a fluid flowing with a constant and uniform velocity v along the gradient direction. If the additional nutation angle caused by this displacement is denoted by $\varphi = \gamma g_1 v \delta \Delta$, it is easily shown that the magnetization components just after the second gradient pulse in the sequence of Figure 2 are $m_x = 0$, $m_y = -m_0 \sin \varphi$ and $m_z = -m_0 \cos \varphi$. Because only m_z is converted into observable magnetization, the observed signal is modulated according to $\cos \varphi$, readily yielding the velocity v if the experiment is repeated for different values of the gradient pulse duration δ . As far as the sequence of Figure 3 is concerned, owing to the phase cycling and to the averages given by equation (4), the same result holds, with, however, a signal reduction by a factor of $\frac{1}{2}$.

3 NMR IMAGING BY RADIOFREQUENCY GRADIENT PULSES

Following Hoult's early experiment,¹ B_1 gradients, as far as NMR imaging is concerned, have found an interesting field of applications since the beginning of the 1980s, essentially in the context of the so-called rotating frame spectroscopic imaging technique (for a comprehensive review of this subject, see Styles⁴). Basically, the experiment is two-dimensional in nature, one dimension being related to spatial information along the axis of the B_1 gradient (X), the other dimension providing chemical shift information. The simplest sequence¹³ consists of application of the B_1 gradient for an incrementable time t_1 , followed by the acquisition of the NMR signal, with which is associated the time variable t_2 . This corresponds to an amplitude-modulated two-dimensional experiment, provided that the increment in t_1 is properly chosen to examine the whole sample size and that the dwell time in t_2 fits the chemical shift range. Owing to the form of the collected signal

$$S(t_1, t_2) = \sin(2\pi Xk) \cos(2\pi \nu t_2) \quad (5)$$

here $k = \gamma g_1 t_1 / 2\pi$, and one obtains, after a double Fourier transform, the chemical shift information in ν_2 and the spatial information in ν_1 . Refinements of the method, including quadrature detection and thus sensitivity improvements,

Figure 2 A pulse sequence for measuring translational diffusion coefficients, with radiofrequency field gradient pulses (g_1). The rf pulses denoted by π and $\pi/2$ are homogeneous. Subscripts indicate rf phases

Figure 3 A simplified version of the pulse sequence of Figure 1. Note the phase cycle of the second gradient pulse, which allows one to retain only contributions from longitudinal magnetization

were published later. Along the same lines, spin density profiles have been obtained through the observation of ^{23}Na resonances.¹⁴

NMR imaging, as it is usually understood, namely, the spatial variation of the spin density pertaining to a single chemical species, can be performed by resorting only to $\mathbf{B}_1$ gradients. Again the method is a sort of transportation of procedures using $\mathbf{B}_0$ gradients. The advantages as well as pitfalls of $\mathbf{B}_1$ gradients (listed above) support the conclusion that, at the present time, $\mathbf{B}_1$ gradients can better be used for NMR microscopy, with applications essentially in the field of materials science.¹⁵ This basic scheme of 2D imaging by $\mathbf{B}_1$ gradients¹⁶ involves at the onset a slice selection procedure. The latter is carried out by the rf gradient of the saddle coil of Figure 1. Selectivity in the Z direction is achieved by a pulse train of the DANTE type,¹⁷ provided that the saddle coil has been purposely designed for presenting a strong $\mathbf{B}_1$ variation along Z . Thereafter the (X, Y) plane can be examined by means of projections along the gradient axis, collected for different orientations of the object with respect to the Z axis. To this end, the experiment, including the initial slice selection, is repeated for as many sample rotations as necessary, performed in a stepped manner around Z . The whole set of data (projections) can be treated with the help of the ‘filtered back projection’ (FBP) algorithm,¹⁸ which provides the image reconstruction in the (X, Y) plane. The pulse sequence for obtaining *one* projection (defined by α , which specifies the angle by which the object has been rotated with respect to its initial position) is sketched in Figure 4. It relies on the nutation angle produced by the $\mathbf{B}_1$ gradient delivered by the simple single turn coil, which can be expressed as

$$2\pi k(X \cos \alpha + Y \sin \alpha + D) \quad (6)$$

where X and Y are the coordinates of the considered elementary magnetization, D is the distance between the

Figure 4 Sequence corresponding to 1D $\mathbf{B}_1$ gradient encoding (profile). The magnetization of interest is selected along the y axis of the rotating frame by means of a DANTE-like pulse train (the relevant $\mathbf{B}_1$ gradient is created by the vertical saddle coil, which is also employed for signal detection). The pseudo-FID (signal) is obtained by application of the read gradient [$g_1(X)$, created by the single turn coil—see Figure 1] along the x direction of the rotating frame. This pseudo-FID reflects nutation, which is spatially dependent. Dots denote data acquisition, which can be performed only when the $g_1(X)$ gradient is turned off because of residual coupling between the two coils

rotating axis and the virtual point where $\mathbf{B}_1$ is zero, and k is related to the time t during which the gradient has been applied ($k = \gamma g_1 t / 2\pi$). The collected signal has the form

$$S(k, \alpha) = \iint \varrho(X, Y) \cos[2\pi k(X \cos \alpha + Y \sin \alpha + D)] dX dY \quad (7)$$

which lends itself to the reconstruction procedure alluded to above (FBP) for obtaining the spin density $\varrho(X, Y)$. The image of a water phantom is shown in Figure 5.

Another approach,¹⁹ based on a nonuniform $\mathbf{B}_1$ gradient created by a toroidal cavity resonator, has been shown to enable spatial resolution of the order of a few micrometers.

Figure 5 A phantom image obtained by B_1 gradient imaging (see Figure 4). Thickness of capillary walls is about $100\ \mu\text{m}$

4 PURELY SPECTROSCOPIC APPLICATIONS OF RADIOFREQUENCY GRADIENT PULSES

The use of B_1 gradients in spectroscopy seems rather promising. As for static gradients, spectral selectivity is the natural field of application. A first example is provided by solvent peak suppression, which can be simply and efficiently performed by means of a DANTE train of B_1 gradient pulses.²⁰ It is based on the way in which a classical DANTE sequence,¹⁷ made of homogeneous hard pulses, acts on a spin system. It can be schematized by $[(\alpha)_x - \tau]_n$. The pulse denoted by $(\alpha)_x$ flips the magnetization by a small angle α around the x axis of the rotating frame; magnetization is then allowed to precess for a time τ . Except for resonances ν' at zero frequency (coinciding with the carrier frequency) or at $\nu' = k/\tau$ (k integer), the next rf pulse will not produce the same nutation, since the corresponding magnetization is no longer in a plane perpendicular to B_1 . In fact, after n cycles, these magnetizations are merely restored toward the Z axis—in other words, to the equilibrium axis. Conversely, for magnetizations at k/τ (including zero frequency), no net precession occurs, and the effect of pulses is *cumulative*, leading to a total nutation angle $n\alpha$. Hence, magnetizations relevant to these frequencies are selectively taken to any location in the (y, z) plane by adjusting n and α . When using B_1 gradient pulses instead of homogeneous (α) pulses, magnetizations at frequencies k/τ are progressively defocused in the course of the n cycles, whereas other magnetizations benefit from the usual behavior of a DANTE sequence, and thus remain along the Z axis. This procedure is rather simple to run, and proves to be very efficient for eliminating the solvent resonance, as shown in Figure 6. It must be emphasized that this is not a saturation process, since the total application of the B_1 field (in the form of a gradient) is, in duration, largely below relaxation times.

Another interesting application of gradients in spectroscopy concerns the so-called selection of coherence pathways, which amounts to avoiding the phase cycling schemes and thus

Figure 6 Solvent peak suppression obtained by applying a DANTE train of B_1 gradient pulses prior to a normal read pulse (bottom). Note the increase of sensitivity with respect to the conventional spectrum (top), owing to the availability of the whole dynamic range of the analog-to-digital converter

reduces the measurement time in two-dimensional correlation experiments. The very first COSY experiment by which quadrature detection in the t_1 time domain could be obtained in a single transient per t_1 value can be schematized as follows:²¹

$$(\pi/2)_x - t_1 - (g_0) - (\pi/2)_x - (g_0) - \text{Acq}(t_2) \quad (8)$$

where $(\pi/2)$ stands for a homogeneous radiofrequency pulse and (g_0) for a static field gradient (B_0) pulse of arbitrary duration. The analog of the sequence in equation (8) with B_1 gradient pulses can be devised by referring to clusters involving homogeneous pulses and one B_1 gradient, which have the same effect as a single B_0 gradient pulse:⁶

$$\begin{aligned} &(\pi/2)_x - t_1 - (\pi/2)_x - (g_1)_y - (\pi/2)_x - (g_1)_y \\ &- (\pi/2)_{-x} - \text{Acq}(t_2) \end{aligned} \quad (9)$$

This sequence has actually been worked out in conjunction with *radial* B_1 gradients²² (such gradients, based on a quadrupolar arrangement, correspond to a spatial variation of B_1 along radii intersecting at the center of the sample, by contrast with the *planar* gradient created by the simple device shown in Figure 1), which imply further clusters of homogeneous pulses for compensating purposes. An even simpler sequence,²³ using planar B_1 gradients, leads exactly to the same result. It has the form

$$(\pi/2)_x - t_1 - (\pi/2)_y (g_1)_x (g_1)_y (\pi/2)_x - \text{Acq}(t_2) \quad (10)$$

It will be briefly analyzed, with the emphasis put on the inherent quadrature prevailing in the t_1 domain. For that purpose, the quantities pertaining to a two-spin- $\frac{1}{2}$ system (A, X) and that exist at the end of the evolution time t_1 will be considered. These are $\hat{I}_x$, $\hat{I}_y$ for in-phase magnetizations, and $2\hat{I}_{A,x}\hat{I}_{X,z}$, $2\hat{I}_{A,y}\hat{I}_{X,z}$ for antiphase magnetizations relative to a spin A, J -coupled to a spin X.²⁴ By combining, on the one hand, rotations due to homogeneous ($\pi/2$) pulses, and, on the other, averaging effects due to $\mathbf{B}_1$ gradient pulses [equation (4)], it turns out that these quantities under the cluster $(\pi/2)_y (g_1)_x (g_1)_y (\pi/2)_x$, transform as

$$\hat{I}_x \rightarrow \frac{1}{2}\hat{I}_y \quad (11)$$

$$\hat{I}_y \rightarrow \frac{1}{2}\hat{I}_x \quad (12)$$

$$2\hat{I}_{A,x}\hat{I}_{X,z} \rightarrow \frac{1}{2}(2\hat{I}_{A,z}\hat{I}_{X,y}) \quad (13)$$

$$2\hat{I}_{A,y}\hat{I}_{X,z} \rightarrow \frac{1}{2}(2\hat{I}_{A,z}\hat{I}_{X,x}) \quad (14)$$

It can be seen that equations (13) and (14) indicate coherence transfers from A to X (cross peaks in the 2D map), whereas equation (11) and (12) will give rise to diagonal peaks, all with a loss of sensitivity by a factor of two. For these four quantities, it can be seen that the x component in t_1 (denoted below by x_1) transforms into a y component in t_2 (denoted below by y_2), and, conversely, that y_1 transforms into x_2 . Now, disregarding a trivial phase angle affecting all magnetization components uniformly, it can be assumed that, under precession, the x component is modulated by a cosine function and the y component by a sine function [$x \propto \cos(2\pi\nu t)$ and $y \propto \sin(2\pi\nu t)$]. Because quadrature detection is physically employed in t_2 , one has

$$\left. \begin{array}{l} x_2 \propto \exp(2i\pi\nu_2 t_2) \\ y_2 \propto i \exp(2i\pi\nu_2 t_2) \end{array} \right\} \quad (15)$$

Referring to the relationships $x_1 \rightarrow y_2$ and $y_1 \rightarrow x_2$, one obtains for x_1 ,

$$\cos(2\pi\nu_1 t_1) i \exp(2i\pi\nu_2 t_2) \quad (16)$$

and for y_1 ,

$$\sin(2\pi\nu_1 t_1) \exp(2i\pi\nu_2 t_2) \quad (17)$$

Since x_1 and y_1 coexist at the end of the t_1 interval, as well as the relevant quantities during t_2 , the total signal can be expressed as the sum of equations (16) and (17):

$$S(t_1, t_2) = i \exp(-2i\pi\nu_1 t_1) \exp(2i\pi\nu_2 t_2) \quad (18)$$

This equation shows that quadrature in t_1 is effective with a single transient (without any phase cycling); S must, however, be subjected to a complex two-dimensional Fourier transform, with the unavoidable phase twist phenomenon and the necessity to display the final spectrum in the magnitude mode.

The next step is to devise a procedure using $\mathbf{B}_1$ gradients that would be the equivalent to the widely used double quantum filtered COSY experiment.²⁵ The latter has two major advantages:

1. attenuation (in principle elimination) of single quantum coherences, especially the one related to the solvent peak;
 2. identical phases for diagonal and cross peaks, which allows the reduction of overlaps between these two types of peaks.
- The objective is still to reduce the measuring time by avoiding phase cycling (a single transient per t_1 value). The interest of such an experiment was demonstrated for $\mathbf{B}_0$ gradients,²⁶ although, in that case, it proved difficult to obtain pure absorption spectra. With $\mathbf{B}_1$ gradients, the basic sequence²⁷ can be schematized as

$$(\pi/2)_x - t_1 - (g_1)_x (2g_1)_y - \text{Acq}(t_2) \quad (19)$$

where $(2g_1)$ indicates a $\mathbf{B}_1$ gradient pulse of duration twice that of (g_1) . Further discussions about the sequence in equation (19) and some of its variants can be found in the literature.²⁸ In order to trace the quantities that survive after the two $\mathbf{B}_1$ gradient pulses, it suffices to resort to the averaging of nutation angles given by equation (4) as was done to obtain the results in equations (11)–(14). This yields

$$\hat{I}_x \rightarrow 0 \quad (20)$$

$$\hat{I}_y \rightarrow 0 \quad (21)$$

$$2\hat{I}_{A,x}\hat{I}_{X,z} \rightarrow 0 \quad (22)$$

$$2\hat{I}_{A,y}\hat{I}_{X,z} \rightarrow \frac{1}{4}(2\hat{I}_{A,y}\hat{I}_{X,z}) + \frac{1}{4}(2\hat{I}_{A,z}\hat{I}_{X,y}) \quad (23)$$

As can be seen from the above results, all single quantum coherences vanish whereas one antiphase magnetization, $(2\hat{I}_{A,y}\hat{I}_{X,z})$, leads to a diagonal peak, $\frac{1}{4}(2\hat{I}_{A,y}\hat{I}_{X,z})$, and a cross peak, $\frac{1}{4}(2\hat{I}_{A,z}\hat{I}_{X,y})$, representing coherence transfer from A to X. It is perfectly clear that the same goal has been achieved as in DQF-COSY, with a single transient per t_1 value. Although quadrature detection in t_1 is no longer an inherent feature of the experiment, it can be retrieved by the time proportional phase incrementation (TPPI) procedure²⁹ applied to the first $\pi/2$ homogeneous pulse. As shown in Figure 7, the experiment affords especially clean spectra.

Finally, it should be mentioned that the use of $\mathbf{B}_1$ gradients is not limited to homonuclear systems: a $\mathbf{B}_1$ gradient pulse can be implemented in a variant of the heteronuclear multiple quantum correlation (HMQC) experiment.³⁰

1 REFOCUSING AND DEPHASING

Rotational echo double resonance (REDOR) NMR is a new analytical spectroscopic technique for solids spinning at the magic angle which has been developed during the last 6 years.¹ REDOR provides a direct measure of heteronuclear dipolar coupling between isolated pairs of labeled nuclei. In a solid with a ^{13}C – ^{15}N labeled pair, for example, the ^{13}C rotational echoes that form each rotor period following a ^1H – ^{13}C cross polarization transfer can be prevented from reaching full intensity by insertion of a ^{15}N π pulse each half rotor period (Figure 1). The ^{15}N pulse in the middle of the evolution period is replaced by a ^{13}C pulse so that isotropic carbon chemical shifts are in phase at the beginning of data acquisition. The REDOR difference (the difference between a ^{13}C NMR spectrum obtained under these conditions and one obtained with no ^{15}N π pulses) has a strong dependence on the ^{13}C – ^{15}N dipolar coupling and hence the ^{13}C – ^{15}N internuclear distance.² REDOR is described as double resonance even though three radiofrequencies (typically ^1H , ^{13}C , and ^{15}N) are used because the protons are removed from the important evolution part of the experiment by resonant decoupling. The dephasing of magnetization in REDOR arises from a local dipolar ^{13}C – ^{15}N field gradient and involves no polarization transfer. REDOR has no dependence on ^{13}C or ^{15}N chemical shift tensors and does not require resolution of a ^{13}C – ^{15}N coupling in the chemical shift dimension.²

The evolution of observable S -spin magnetization for a single crystallite on resonance under magic angle spinning and an I – S dipolar coupling is shown in Figure 2 (left). Each dot represents the result of evolution for an equal fraction of a rotor period, with a minor homogeneous decay superimposed for display purposes. At the beginning of the rotor cycle, the magnetization is the observable, $\langle \hat{S}_x \rangle$. Under sample rotation and I – S dipolar coupling, the observable magnetization is transformed into nonobservable bilinear coherence, $\langle \hat{I}_z \hat{S}_y \rangle$, and then back into $\langle \hat{S}_x \rangle$. By the end of the rotor cycle the full observable magnetization has been recovered. For a collection of crystallites in a powder, individual phase accumulations (the product of resonance frequency and time) vary in size and sign depending on crystallite orientation in the magnetic

Figure 1 Pulse sequence for a version of REDOR ^{13}C NMR. Two equally spaced, ^{15}N 180° pulses per rotor period result in the dephasing of transverse carbon magnetization produced by a cross-polarization (CP) transfer from dipolar-coupled protons. Carbon–nitrogen dipolar coupling determines the extent of dephasing. A ^{13}C 180° pulse replaces the ^{15}N pulse in the middle of the dephasing period and refocuses isotropic ^{13}C chemical shift differences at the beginning of data acquisition. After the CP transfer, resonant decoupling removes the protons from the experiment. The illustration is for four rotor cycles

field. This causes phase interference during the rotor cycle and an apparent decay of the observable signal for the powder. Nevertheless, because the magnetization from each crystallite refocuses completely, the dephasing for the powder is also refocused into a full rotational echo at the end of the rotor cycle.

However, even for a single crystallite, the refocusing is incomplete in the presence of dephasing I -spin π pulses (Figure 2, right). Evolution for the crystallite is identical to that shown at the left of the figure between times ‘1’ and ‘2’. The I -spin inverting π pulse, which ends at time ‘3’, changes the sign of $\langle \hat{I}_z \hat{S}_y \rangle$. This process is repeated under the second I -spin π pulse which ends at time ‘5’. At the end of the rotor cycle (time ‘6’), the transformation of bilinear coherence created during the rotor cycle into observable magnetization is incomplete. For a powder, a rotational echo of diminished intensity is observed. The extent of the diminution depends on the I – S coupling. The diminution is maximum for two dephasing pulses and is independent of their exact placement so long as the pulse spacing is one-half of the rotor period.²

2 REDOR DEPHASING FOR RECRYSTALLIZED LABELED ALANINES

The results of a REDOR experiment performed using the pulse sequence of Figure 1 on an equimolar, recrystallized mixture of L-[2- ^{13}C , ^{15}N]alanine and L-[1- ^{13}C]alanine are shown in Figure 3.³ The full echo ^{13}C NMR spectrum (S_0) after two rotor cycles with no dephasing is at the bottom of the Figure, and the REDOR difference ($\Delta S = S_0 - S$, where S is the spectrum with dephasing) as a function of the number of rotor cycles, is shown at the top of the Figure. The 900 Hz intramolecular ^{13}C – ^{15}N coupling results in a sizeable ΔS for the methine carbon atom after only two rotor cycles; this ΔS reaches a maximum after four rotor cycles, and then oscillates in amplitude. The average 100 Hz intermolecular coupling produces a small carboxyl carbon atom ΔS after two rotor cycles, which increases monotonically with dephasing time.

Figure 2 Schematic diagram of the evolution of the IS density matrix for a single crystal under magic angle spinning and $I-S$ dipolar coupling during a REDOR pulse sequence with no dephasing pulses (left) and with dephasing pulses (right)

Figure 3 The 50.3-MHz REDOR ^{13}C NMR spectra of an equimolar, recrystallized mixture of L-[2- ^{13}C , ^{15}N]alanine and L-[1- ^{13}C]alanine, as a function of the number of rotor cycles. A full echo spectrum (S_0) after two rotor cycles is shown at the bottom of the Figure and REDOR difference spectra (ΔS) at the top. Magic angle spinning was at 2702 Hz

The $\Delta S/S_0$ ratios for both carbon atoms have the same dependence on the dimensionless parameter, λ_D (Figure 4, solid circles and squares). The theoretical dependence (Figure 4, solid line) was calculated by performing an isotropic powder average over the dephasing for individual crystallites (Figure 2, right). Thus, the angular dependence of the dipolar interaction is suppressed. The resulting universal dephasing behavior needs to be calculated only once for all heteronuclear spin-1/2 pairs. (REDOR applications also include quadrupolar nuclei like ^2H , with either direct observation of deuterium or indirect observation through REDOR dephasing. Calculation of the theoretical $\Delta S/S_0$ behavior is slightly more complicated.)⁴

Figure 4 Observed dependence of $\Delta S/S_0$ on the universal parameter, λ_D , for the ^{13}C - ^{15}N double-labeled alanine mixture of Figure 3. (N is the number of rotor cycles with dephasing, D is the dipolar coupling constant, and T_r is the rotor period)

A few experimental values of $\Delta S/S_0$ determine λ_D , which then establishes D since the total dephasing time (the product of the number of rotor cycles of dephasing and the rotor period) is known. Because $D = \gamma_I \gamma_S \hbar / 2\pi r^3$, the observed dephasing can be translated into an internuclear distance directly. If $\Delta S/S_0$ and hence D are known experimentally to 10%, the distance is known with 2% accuracy. Weak dipolar couplings associated with large internuclear distances can be effectively amplified in REDOR by simply allowing the rotor to go around. The only practical problem is holding the echo train together. This depends on the technical difficulty of completely decoupling the protons, which may require low temperatures to suppress kHz regime molecular motions.⁵ Translating dipolar couplings into distances in the presence of large-amplitude motions involves specifying a model for the motion.⁶

3 LONG-RANGE COUPLINGS AND THE NATURAL-ABUNDANCE BACKGROUND

In the early applications of REDOR to C–N distance determinations in peptides, relatively few dephasing pulses were used so that sometimes large natural-abundance corrections were necessary.⁷ More recently, increased dephasing has been possible as a result of the development of phase routing schemes⁸ (Figure 5) that eliminate the dependence of REDOR determinations on frequency offsets and pulse imperfections.⁹

For example, the ^{13}C signal for the label in the nine-residue emerimicin fragment, Ac-Phe-[1- ^{13}C]MeA₂-MeA-MeA-Val-[^{15}N]Gly₆-Leu-MeA-MeA-O-Bzl, where Ac = acetyl, Phe = phenylalanine, MeA = methylalanine, Val = valine, Gly = glycine, Leu = leucine, Bzl = benzyl is not resolved from that of natural-abundance peptide carbonyl carbon atoms, which make a constant 7.7% contribution to the full echo signal, S_0 . This correction can either be measured in a separate experiment on a natural-abundance sample, or calculated from the known structure.¹⁰ In addition, the natural-abundance ^{13}C carbonyls of Val₅ and Gly₆ are, respectively, one and two bonds away from the ^{15}N label and so will make a contribution to ΔS that reaches a maximum value of 2% by about $N_c = 16$. The other natural-abundance carbonyl ^{13}C atoms are all farther away from the ^{15}N label than is the

Figure 5 REDOR pulse sequence with dephasing π pulses on both the nitrogen and carbon channels. The pulses are applied using an xy -8 phase cycling scheme to eliminate offset effects and pulse imperfections. Signal acquisition begins two rotor cycles after the completion of a full $8N$ rotor cycles of dephasing. CP = cross polarization. Acq = acquisition

Figure 6 Observed dependence of $\Delta S/S_0$ on the universal parameter, λ_D , for a ^{13}C – ^{15}N double-labeled fragment of emerimicin. The pulse sequence of Figure 5 was used. The experimental results (solid circles) are in agreement with calculation (solid line) assuming a ^{13}C – ^{15}N dipolar coupling of 40 Hz corresponding to a C–N distance of $4.1 \pm 0.1 \text{ \AA}$. The natural-abundance correction to $\Delta S/S_0$ at $N_c = 8$ is 50% and at $N_c = 100$ is 4%

carbonyl label at MeA₂. Thus, for $N_c > 32$, the observed ΔS is dominated by the coupling of the ^{15}N – ^{13}C labels and additional natural-abundance corrections are unimportant. By $N_c = 96$, $\Delta S/S_0$ is greater than 0.7 (Figure 6), consistent with a D value of 40 Hz, corresponding to a C–N distance of $4.2 \pm 0.1 \text{ \AA}$. The distance by X-ray analysis¹¹ is $4.16 \text{ \AA}$. The natural-abundance correction to D is less than 2 Hz when $N_c = 96$, which means that less than a 0.05- $\text{\AA}$ correction for the C–N distance is required. The agreement between X-ray and REDOR determinations of the [1- ^{13}C]MeA₂–[^{15}N]Gly₆ distance for this calibration sample for $N_c = 8$ to $N_c = 112$

Figure 7 Pulse sequence for TEDOR I – S NMR. Following a cross-polarization (CP) transfer from abundant protons to generate initial I -spin magnetization, the effect of the protons is removed by resonant decoupling. The π pulses are shown separated by one-half rotor periods. The coherence transfer is achieved by simultaneous $\pi/2$ pulses in the middle of the evolution period. The solid circles represent observable magnetization

Figure 8 Schematic diagram of the evolution of the density matrix for a powder during the TEDOR pulse sequence of Figure 7 before the coherence transfer pulses (left) and after the application of the transfer pulses (right). The phase angle between $\langle \hat{I}_x \rangle$ and $\langle \hat{I}_y \hat{S}_z \rangle$ for each rotor cycle is indicated by the solid circles and is calculated using the technique illustrated in Figure 2 (right) together with a powder average. The effect of the 90° pulses is to permute I and S subscript indices

confirms that with the compensation of the $xy-8$ phase cycling scheme, hundreds of dephasing pulses can be used with no significant accumulation of error for a REDOR difference.¹⁰ A few, accurate long range distance determinations are often sufficient to establish unambiguously the local conformation of a peptide or protein.¹²

Figure 9 Transferred-echo double-resonance (top) and cross-polarization, magic angle spinning (CP MAS, bottom) ^{13}C NMR spectra of a recrystallized equimolar mixture of L-[2- ^{13}C , ^{15}N]alanine and L-[1- ^{13}C]alanine. The TEDOR spectrum was obtained using three rotor cycles each of dephasing and refocusing. This is insufficient to generate significant carboxyl-carbon magnetization because the average intermolecular C–N dipolar coupling is weak

Figure 10 Pulse sequence for TEDOR combined with REDOR. The TEDOR part of the experiment (which for this illustration extends over the first four rotor cycles following the H–N cross polarization transfer) selects ^{13}C magnetization by a coherence transfer from ^{15}N . The REDOR part of the experiment (broken brackets) immediately follows the TEDOR preparation and measures dipolar coupling of the selected ^{13}C to ^{19}F . REDOR dephasing is performed using the phase-routing scheme illustrated in Figure 5. Two rotor cycles are added to the sequence so that the start of data acquisition is not coincident with a pulse

Figure 11 TEDOR-REDOR ^{13}C NMR spectra of a ^{19}F , ^{13}C , ^{15}N -labeled emerimicin (see Figure 6). The TEDOR spectrum (bottom) was obtained using an N–C coherence transfer as illustrated in Figure 7. The TEDOR-REDOR difference spectrum (the difference between TEDOR spectra with and without dephasing REDOR pulses) is shown at the top of the Figure. This spectrum was obtained by ^{19}F dephasing of the ^{15}N -TEDOR-selected ^{13}C magnetization over 40 rotor cycles

Background corrections for ^{13}C -observe ^{15}N -dephase REDOR are relatively simple to calculate because the ^{15}N natural abundance is low and γ_{N} is small. A measured value involves a separate sample with no ^{15}N label. The minor, observed $\Delta S/S_0$ for the single-labeled sample is then usually just subtracted from that for the double-labeled sample.³ The correction is more involved for ^{13}C - ^{31}P and ^{13}C - ^{19}F pairs. For example, a ^{19}F -observe ^{13}C -dephase REDOR experiment designed to measure the dipolar coupling for a labeled ^{19}F - ^{13}C pair separated by 10 Å must take into account the sizeable number of natural-abundance ^{13}C atoms within dephasing range of the ^{19}F . One way¹³ to interpret the observed $\Delta S/S_0$ is to generate a model lattice with 1% randomly distributed ^{13}C . If all ^{13}C - ^{13}C coupling is ignored, the ^{19}F -observed, ^{13}C -dephase REDOR ΔS can be interpreted in terms of a collection of independent, $^{19}\text{F}(\text{label})$ - $^{13}\text{C}(\text{label})$ - $^{13}\text{C}(\text{natural abundance})$, three-spin clusters, whose dipolar-tensor orientations are known from the lattice parameters.

4 COHERENCE TRANSFER AND SELECTIVITY

Sometimes a natural-abundance background cannot be measured or calculated easily. In this situation, the dipolar-coupled spins can be selected from among the background of uncoupled spins by a coherence transfer from one spin of

the heteronuclear pair to the other. The pulse sequence for this selection is shown in Figure 7. Transverse magnetization is first established in the I -spin system by a cross-polarization transfer from abundant protons. The dephasing of I -spin magnetization by dipolar-coupled S spins through rotor-synchronized S -spin π pulses leads to a bilinear coherence (Figure 8, left) that is transferred by an I, S pair of $\pi/2$ pulses (Figure 8, shaded arrow). These pulses occur together at the completion of a rotor cycle (Figure 7) and interchange the indices of the bilinear coherence. Finally, the transferred bilinear coherence is transformed into observable S -spin transverse magnetization by rotor-synchronized I -spin π pulses (Figure 8, right). The entire procedure is called transferred echo double resonance (TEDOR).¹⁴ TEDOR is a rotor-synchronized solid state experiment which is based on some of the same coherence transfer principles as the INEPT solution state experiment.

The results of a TEDOR experiment using the pulse sequence of Figure 7 performed on the mixed double-labeled alanine sample discussed above are shown in Figure 9. Proton polarization is first transferred to nitrogen atoms. Then three rotor cycles are used to create bilinear ^{15}N - ^{13}C coherence, and three more rotor cycles to produce observable methine carbon atom magnetization following the coherence transfer. The TEDOR theoretical transfer efficiency¹⁴ is 50% compared with the observed 35% (Figure 9). Because TEDOR is not a difference experiment, TEDOR has the same theoretical sensitivity as REDOR. No sizeable carboxyl

Figure 12 Two schemes for REDOR. (Left) Acquisition of a time domain signal follows evolution during which dephasing pulses diminish observable magnetization and create nonobservable I - S bilinear coherence. This scheme is suitable for multiline spectra and a separate $\Delta S/S_0$ is measured for each line in the spectrum. The dependence on λ_D is determined by varying the number of rotor cycles. (Right) Synchronous detection of a time domain signal during evolution is suitable for a single-line spectrum. The observed S/S_0 is $1 - (\Delta S/S_0)$. AQ = acquisition; SAQ = synchronous acquisition

carbon magnetization is observed in Figure 9 because the short evolution time was insufficient for the weak intermolecular ^{15}N – ^{13}C coupling to create significant bilinear coherence. If there had been a collection of nitrogen atoms all with comparable strong, couplings to carbon atoms, the TEDOR coherence transfer could still have been made selective by alternating the sign of the starting nitrogen magnetization for just one type of ^{15}N by DANTE inversion of the selected nitrogen atom signal every other scan.¹⁵ The sign of the transferred bilinear coherence would then alternate, as would that of the observed carbon atom magnetization corresponding to the selected ^{15}N – ^{13}C coupling. Data routing could then discriminate between carbon signals.

5 COMBINATION EXPERIMENTS AND SYNCHRONOUS DETECTION

TEDOR can be used alone or in combination to make highly selective TEDOR–TEDOR and TEDOR–REDOR experiments.¹⁶ The pulse sequence for the latter is illustrated in Figure 10. A TEDOR sequence is tailored to select the carbonyl carbon atom signal of residue 4 of a ^{19}F , ^{13}C , ^{15}N triple-labeled emerimicin fragment (Figure 11). The ^{15}N – ^{13}C selected magnetization is then dephased by REDOR ^{19}F π pulses resulting in the determination of a selected 8-Å C–F distance. This combination experiment involves four radiofrequencies in the same sequence which is possible using transmission-line probe technology.¹⁷ The tuning elements in these probes are outside the magnet in a large, shielded box with isolation of all radiofrequencies, making high power on four channels practical.¹⁸

The observed signal in the TEDOR–REDOR experiment can be detected either as part of a two-dimensional experiment in which full S and S_0 spectra are obtained by normal

Figure 13 Simulation of X-spin REDOR dephasing of I – S TEDOR-selected S -spin magnetization (solid line). The simulation assumed an I – S coherence transfer after two rotor cycles of dephasing, followed by two rotor cycles of transformation of coherence into observable S -spin magnetization (see Figure 7). For $S/S_0 > 0.5$, the simulation is almost independent of orientation of I – S and S – X dipolar tensors (results not shown) and closely matches that for a full isotropic powder (dotted line). All simulations were performed assuming that the I – S coupling was 1.2 kHz, the S – X coupling was 100 Hz, and the magic angle spinning was 5 kHz

acquisition starting with a rotor cycle (Figure 12, left), or synchronously with one sampling per rotor cycle (Figure 12, right). The former is used for complicated spectra with more than one resonance even after selection by TEDOR. The latter is used for the simple, one-line spectra that usually result from a TEDOR preparation. Synchronous detection² has the sensitivity advantage of generating the entire REDOR dephasing pattern in real time. The dipolar evolution dimension can be mapped by variation of the number of rotor cycles,¹ or variation of the position of the dephasing pulse within the rotor period.² The latter has a constant total dipolar evolution time which eliminates the echo-train lifetime from the analysis. In both of these two-dimensional methods, spins which contribute to the S -spin signal but have no I – S coupling (a common situation for a natural-abundance background) do not interfere with the determination of the I – S interaction.¹⁶ Such spins produce a constant offset in the dipolar time domain and so a zero-frequency spike in the dipolar frequency domain. The I – S coupling is determined by the width of the dipolar spectrum.²

Even an efficient TEDOR transfer does not result in observable magnetization associated with an isotropic powder. Thus, some crystallite orientations are discriminated against depending on the orientation of the IS and SX dipolar tensors in an I – S – X three-spin TEDOR–REDOR experiment. Nevertheless, following an efficient I – S TEDOR transfer, the *initial* S -observe, X -dephase REDOR behavior depends only on the size of the dipolar tensors and not on their orientation (Figure 13). Thus, interpretation of the 20% dephasing (Figure 14) in a TEDOR–REDOR experiment on the triple-labeled peptide of Figure 11 does not require knowledge of ^{15}N – ^{13}C – ^{19}F geometry in order to extract a C–F distance.¹⁶ This will be the situation for most long-range distance determinations in general, simply because little dephasing is observed and determination of the dipolar coupling is based on the initial S/S_0 behavior. However, for systems with stronger couplings, Fourier transforms of the TEDOR–REDOR dipolar evolution offer the opportunity to establish geometry by comparisons with theoretical dipolar lineshapes (Figure 15).

Figure 14 Synchronously sampled time domain ^{13}C signal of a ^{19}F , ^{15}N , ^{13}C -triple-labeled emerimicin diluted by natural-abundance peptide. The ^{15}N TEDOR-selected ^{13}C signal is sampled once each rotor period either with (S) or without (S_0) ^{19}F dephasing pulses. Magic angle spinning was at 5 kHz

Figure 15 Dipolar spectra obtained by Fourier transforms of time domain simulations performed as described in the caption to Figure 13. The widths of both dipolar spectra are determined by the 100-Hz $S-X$ coupling. Details of the lineshape are determined by orientation of $I-S$ and $S-X$ dipolar tensors

1 INTRODUCTION

Selective excitation first became important in the field of magnetic resonance imaging, where it is used to select slices or volumes in an object.¹ It was only with the development of DANTE sequences,² which allowed the implementation of amplitude modulated pulses on conventional spectrometers, and the subsequent availability of fully modulatable low-power transmitters on modern spectrometers, that shaped pulses became important in high-resolution spectroscopy. While there are many facets in common between selective excitation in imaging experiments and in high-resolution experiments, there are nevertheless some differences in what is important and what can be achieved. (The phase problem, for example, is much less crucial in imaging than in spectroscopy). This article is directed toward selective excitation techniques for high-resolution spectroscopy, and a related article by Maudsley, see *Selective Excitation in MRI and MR Spectroscopy*, is biased toward imaging. Selective pulses are also considered in the articles by Warren, *Shaped Pulses*, Morris, *Complex Radiofrequency Pulses*, and Young, *Selective Excitation Methods: Artifacts*, and techniques using selective pulses can be found in the articles by Bodenhausen, *Selective Hartmann–Hahn Transfer in Liquids* and *Selective NOESY*, and Rossi, *Selective Relaxation Techniques in Biological NMR*. Reviews covering selective pulses and their applications in high-resolution NMR include those by Warren and Silver,³ Freeman,⁴ and Emsley.⁵

The idea behind the majority of high-resolution NMR experiments that utilize selective pulses is that more information can be obtained if the spectral region affected by the pulses in the experiment is reduced. This increase in information can take two forms. Firstly, by reducing the spectral width the digital resolution of the spectrum can be increased, revealing aspects of the spectrum that were previously unresolvable. Secondly, restriction of the spectral range allows one to manipulate the spins in new ways (we are able to treat homonuclear systems in a similar way to heteronuclear systems), so that the spectra convey new information, which may have been previously unobtainable.

Nonselective excitation is usually achieved by applying a short, high-power, pulse to the spin system. Because the pulse is short, we know that its frequency response will be very broad (the bandwidth of the frequency response is proportional to the inverse pulse length).^{6–9} On the other hand, a long, low-power pulse could have a very narrow bandwidth. In addition to having a narrow *bandwidth*, an ideal selective pulse should have a narrow *transition region* between the part of the response that is excited, and that which is not affected at all. In order to achieve this, we use amplitude- (and phase-) modulated pulses.

To approach the problem of selective excitation we must first be able to predict how a particular arbitrarily shaped time domain pulse affects the spin system to produce a particular frequency domain magnetization. The Fourier transform would appear to be an ideal candidate for this purpose. The Fourier transform of a function $f(t)$ is defined as⁶

$$F(\omega) = \int_{-\infty}^{+\infty} f(t) \exp\{-i\omega t\} dt \quad (1)$$

We see from the above formula that the Fourier transform has a reciprocal property: if $F(-\omega)$ is the transform of $f(t)$, then $f(-t)$ is the transform of $F(\omega)$. It is this feature of the Fourier transform that allows us to do the inverse transform, and which makes it so attractive as a method of determining pulse shapes. For example, if a ‘top hat’ frequency domain response is desired, the appropriate pulse shape would be the inverse Fourier transform of a ‘top hat’, i.e. a sinc function as shown in Figure 1.^{6,10} At the same time we can see how a normal rectangular pulse is particularly poor in terms of selectivity, since its transform is a sinc function having extensive ‘wiggles’ in the frequency domain. Indeed, a useful concept arises from Fourier transform theory, which is that if the first noncontinuous derivative of $f(t)$ is the a th, then $F(\omega)$ falls off as $(1/\omega)^a$ at large ω . For the square pulse the first derivative is infinite (i.e. impulsive) at the edges of the pulses, and the excitation falls off as $1/\omega$.

With this in mind we introduce the Gaussian as another useful function, since a Gaussian can be differentiated an infinite number of times. Indeed, the first use of Gaussian-shaped pulses in NMR spectroscopy was proposed by Bauer et al.¹¹ on the grounds of its Fourier transform properties; the transform of a Gaussian is another Gaussian (see Figure 1). The Fourier transform would thus appear to be a particularly convenient method for linking the two domains.

The shift theorem of the Fourier transform can be used to derive a very important result. The theorem states that if $f(t)$ is the transform of $F(\omega)$, then $f(t - \tau)$ has the transform $\exp\{-2\pi i\omega\tau\}F(\omega)$. The Fourier transforms shown in Figure 1(a)–Figure 11(c), are for functions centered at $t = 0$, i.e., the first half of the pulse was applied during negative time. The shift theorem tells us that if a function is shifted by an amount τ , the Fourier components will all retain the same amplitudes, but they will have a *phase shift proportional to ω* . This situation is illustrated for a (truncated) Gaussian pulse starting at $t = 0$ in Figure 1(d). Since we cannot turn on the transmitter before the beginning of the experiment this would be the situation present in any NMR experiment using any pulse shape, in as far as can be predicted by the Fourier transform. (*Note added in proof*. It has very recently been demonstrated that this situation can in fact be avoided, and that

Figure 1 Fourier transforms of some common time-domain shape functions. All the pulses are on the same scales in which the time domain is 150 ms long and the frequency domain is 200 Hz wide. In (a)–(c) are shown the responses to a truncated sinc, a rectangle, and a truncated Gaussian, all centered at $t = 0$, while (d) shows the response to a Gaussian which commences at $t = 0$. The vertical scales are arbitrary. (Reproduced by permission from Emsley⁶⁵)

a pure-phase response can be obtained with pulses predicted using the Fourier transform.⁷⁹

Fortunately, this is not the whole story, and in fact the Fourier transform is only of limited validity in predicting responses because it is only applicable in the linear response regime.^{6,12} The NMR response is highly nonlinear (doubling the pulse length from 90° to 180° does not double the signal intensity). In order to obtain an exact description of the NMR response we must turn to a solution of the quantum mechanical equations of motion for a spin in an external field. For a time-independent (i.e. constant amplitude and phase) pulse, these equations can be solved analytically to yield⁷⁻⁹

$$\begin{aligned}
 \langle \hat{I}_z(t) \rangle &= -\langle \hat{I}_y(0) \rangle \sin \theta \sin \beta_{\text{eff}} \\
 &\quad + \langle \hat{I}_x(0) \rangle (1 - \cos \beta_{\text{eff}}) \cos \theta \sin \theta \\
 &\quad + \langle \hat{I}_z(0) \rangle (\cos \beta_{\text{eff}} \sin^2 \theta + \cos^2 \theta) \\
 \langle \hat{I}_y(t) \rangle &= \langle \hat{I}_y(0) \rangle \cos \beta_{\text{eff}} + \langle \hat{I}_x(0) \rangle \cos \theta \sin \beta_{\text{eff}} \\
 &\quad - \langle \hat{I}_z(0) \rangle \sin \theta \sin \beta_{\text{eff}} \\
 \langle \hat{I}_x(t) \rangle &= \langle \hat{I}_y(0) \rangle \cos \theta \sin \beta_{\text{eff}} \\
 &\quad + \langle \hat{I}_x(0) \rangle (\cos \beta_{\text{eff}} \cos^2 \theta + \sin^2 \theta) \\
 &\quad + \langle \hat{I}_z(0) \rangle (1 - \cos \beta_{\text{eff}}) \cos \theta \sin \theta
 \end{aligned} \quad (2)$$

where the $\langle \hat{I}_k(t) \rangle$, $k = x, y, z$, correspond to the expectation values of the angular momentum operators in the rotating frame, where θ is the tilt angle of the effective field with respect to the z axis of the rotating frame, $\tan \theta = \omega_1/\Omega$, and β_{eff} is the flip angle about the effective field, $\beta_{\text{eff}} = \sqrt{(\omega_1^2 + \Omega^2)}t$. ω_1 is the amplitude of the applied radiofrequency field in rad s^{-1} , and $\Omega = \omega - \omega_0$ is the frequency offset from the transmitter frequency ω_0 . The magnetization precesses around the effective field $\mathbf{B}^{\text{eff}}$ at angular frequency $\omega^{\text{eff}} = \sqrt{(\omega_1^2 + \Omega^2)}$, as illustrated in Figure 2. Although they are only valid when $\mathbf{B}^{\text{eff}}$ is not time dependent, equation (2) forms the basis of the exact calculations for all the responses calculated in this article (and in most other articles concerned with the response of a single spin). Solutions for responses to time-dependent pulses can be obtained ‘numerically’ by solving the problem in a stepwise manner, i.e. by dividing the pulse into sufficiently small increments so that we may neglect the variation in amplitude during each increment, and merely consider the variation from step to step. We shall refer to this technique as ‘numerical integration’. The enormous disadvantage of this technique as compared with the Fourier transform is that we cannot readily do the inverse operation. On the other hand, we can imagine that by exploiting the nonlinear response of the NMR system, we may be able to overcome the phase problem.

2 EXCITATION PULSES

The limit of the validity of the linear response is found to be to small excursions from the z axis.^{3,12} Thus the response to simple pulses with small flip angles can be predicted using the Fourier transform. Even up to around 90°, the deviations from exact behavior are not too large. In this case the phase gradient

Figure 2 In the rotating frame, the magnetization precesses in a cone about a static field ω_{eff} which is the resultant of its offset from the frequency of rotation of the frame, $\Omega = (\omega - \omega_0)$, and the applied field, ω_1 . (Reproduced by permission from Emsley.⁶⁵)

in the transverse magnetization after a selective pulse is linear. Therefore it is, in principle, for simple one-dimensional spectra, possible to apply a first-order phase correction, but as a result of the magnitude of the errors this is usually not possible in practice without introducing large baseline rolls into the spectra. In more advanced pulse experiments involving coherence transfer phenomena the implications are more important since the pulse will not only create in-phase magnetization, but also at least in part antiphase magnetization. In general it is therefore not sufficient merely to apply a baseline correction to the spectra.

If the pulse is used to excite a region of the spectrum containing no scalar couplings, or a spectrum in which the couplings are small compared with the region being excited, then the pulse sequence:

$$90_{\text{soft}}^\circ - 180_{\text{hard}}^\circ - \tau - \text{Acquire}$$

can be used to refocus the magnetization.¹³ However the extension of the length is not welcome since it will increase losses due to relaxation. More importantly, this approach will not work at all to refocus coupled spins and will actually make the phase error worse in such cases. In contrast, if the whole pulse is soft, the coupling partners of a multiplet are not affected and the evolution of the magnetization due to couplings will be refocused in exactly the same way as if it were due to chemical shifts.

Freeman and co-workers^{14,15} proposed the use of a series of pulse shapes, including the half Gaussian, as a means of eliminating the phase errors inherent in selective excitation. Although these pulses do not in themselves produce

magnetization with constant phase, spectra having constant phase can be obtained by adding together the results of two pulse sequences involving the half Gaussian with a hard 180° purging pulse on alternate scans. This has the effect of canceling out the y component of the magnetization while retaining the x component.

More straightforward solutions to the phase problem involve pulses which produce in-phase responses by exploiting the nonlinear behavior of the spin system. There now exists a fairly wide class of pulses in this category which range from the very simple to the extraordinarily complex.^{16–27} We provide first an example of the simplest (and perhaps most useful) solution, and then a brief outline of some of the more complex solutions.

The simplest solution to the phase problem is to use a Gaussian-shaped pulse having an on-resonance flip angle of 270° . The response has a much improved phase behavior compared with that of the conventional 90° Gaussian pulse.¹⁶ In Figure 3 we show the I_x and I_y responses of 90° and 270° Gaussian pulses as a function of offset, and in Figure 4 we show the effect this has on an experimental spectrum of a multiplet in 2-phenylcyclopropanecarboxylic acid methyl ester.

The 270° Gaussian pulses provide a reasonable approximation to in-phase excitation which is sufficient for the majority of applications, especially those that are multiplet selective (see Section 7). However, the improvement in phase properties is at the expense of top-hat selectivity, and there is nevertheless a residual phase dispersion. Using more complex solutions, a more demanding frequency response can be achieved. Many proposals have been made to solve this problem, which (limiting the choice to purely amplitude modulated pulses) can be broadly divided into two categories. The first relies on dividing a trial pulse into many discrete intervals, and varying the rf amplitude in each interval until the response closely approaches a target function.^{17,18,28} Several degrees of sophistication can be employed toward this end, including the optimal control techniques first used by Conolly

Figure 3 I_x and I_y responses of a 90° and a 270° Gaussian pulse. In both cases the pulse was 50 ms in duration and the pulses were truncated at 2.5% of the maximum value. (Reproduced by permission from Emsley⁶⁵)

Figure 4 (a) Nonselective 400 MHz proton spectrum of a mixture of *cis*- and *trans*-2-phenylcyclopropanecarboxylic acid methyl ester recorded on a Bruker AM-400 spectrometer equipped with an Oxford Research Systems selective excitation unit. (b) Spectrum of the M multiplet (see inset) obtained with a 90° Gaussian pulse (33 ms duration) without phase correction. (c) Same spectrum in positive absorption with a large frequency dependent phase correction. (d) Multiplet excited with a 270° Gaussian pulse (33 ms duration). No frequency dependent phase correction was applied to (d). The frequency domain response outside the region shown is flat

and Macovski to obtain a magnitude response,²⁹ and subsequently by Smith et al.²⁸ to obtain an in-phase response, the conjugate gradient method first used by Murdoch et al.⁷⁸ (once again to obtain a magnitude response), and the linearization of the Bloch equations due to Ngo and Morris.¹⁸ These methods provide excellent results, with those of Ngo and Morris approaching very closely an ideal response. However, the resulting envelopes require as many as 100 to 500 independent parameters to be defined, making their practical implementation awkward, and normally resulting in relatively long pulses to achieve a particular selectivity.

The second category of pulses includes those which are optimizations of analytical pulse forms.^{19–26} The most popular of these are pulses defined by either a sum of Gaussians^{22,24} or a Fourier series.^{20,21,23} If the pulse is represented as a sum of Gaussians (a so-called Gaussian pulse cascade) the rf is defined by

$$\begin{aligned}\hat{\mathcal{H}}_1(t) &= \omega_1(t) \hat{I}_x \\ &= \left(\sum_{n=1}^N A_n \exp\{-B_n(t - t_n^{\max})^2\} \right) \omega \hat{I}_x\end{aligned}\quad (3)$$

where ω is the rf field in radians per second. This function represents an envelope of duration t_p consisting of a superposition of N Gaussians, where for the n th Gaussian the position

Table 1 (a) Parameters for the SEEK-3 and G^4 Gaussian Pulse Cascades^{5,22}

Pulse	$n =$	1	2	3	4
SEEK-3	$t^{\max}/t_p$	21.0	71.9	46.9	
	A	2.3	18.2	-12.7	
	$2\Delta t_{\frac{1}{2}}/t_p$	19.0	18.6	19.6

	A	0.62	0.72	-0.91	-0.33
	$2\Delta t_{\frac{1}{2}}/t_p$	17.2	12.9	11.9	13.9

Table 1 (b) Parameters for the E-BURP-2 Pulse^{21,23}

n	A_n	B_n
0	0.26	—
1	0.91	-0.12
2	0.45	-1.79
3	-1.31	0.01
4	-0.12	0.41
5	0.03	0.08
6	0.01	0.07
7	0.06	0.01
8	0.01	-0.04
9	-0.02	-0.01
10	-0.01	0.00

of the maximum is given by $t_n^{\max}$, the peak amplitude by A_n , and the width by

$$B_n = \frac{\ln 2}{(\Delta t_{\frac{1}{2}}^n)^2} \quad (4)$$

$\Delta t_{\frac{1}{2}}^n$ being the width at halfheight. Using this function pulses have been developed for inversion with $N = 3$ and for inphase excitation with $N = 4$, which are fully defined by only nine and 12 independent parameters respectively. In the case of the Fourier series pulses, introduced simultaneously by Morris et al.²⁰ and by Geen and co-workers,^{21,23} the rf is defined by a function of the form

$$\hat{\mathcal{H}}_1(t) = \left\{ A_0 + \sum_{n=1}^N [A_n \cos(n\omega t) + B_n \sin(n\omega t)] \right\} \omega \hat{I}_x \quad (5)$$

The Fourier coefficients $A_0, A_1, \dots$ and $B_1, B_2, \dots$ are the free parameters available for optimization. The series is usually truncated at values of $N < 10$, thereby reducing the number of variable parameters to less than 20. The parameters for both types of pulse are optimized using some sort of computer method by minimizing the deviation with respect to a target function. Some of the results of these techniques are illustrated in Figure 5 where we show the simulated performance of a range of different selective excitation pulses [the parameters describing the various shapes are given in Tables 1(a) and 1(b)]. It can be appreciated that the improvement in going from the original 90° Gaussian pulses to the more sophisticated pulses such as the G^4 Gaussian pulse cascade is really quite remarkable (Figure 5).

Figure 5 A comparison of the (simulated) performance of a 90° Gaussian,¹¹ a 270° Gaussian,¹⁶ an E-BURP-2 Fourier series pulse,²³ a SEEK-3 Gaussian pulse cascade,⁵ and a G^4 Gaussian pulse cascade.²² Parameters for the last three pulses can be found in Table 1. The Figure shows the expected lineshape and amplitude for resonances situated in a region ± 80 Hz from resonance in 8 Hz steps. (Reproduced by permission from Emsley⁶⁵)

3 INVERSION PULSES

Inversion pulses are developed in the same way as excitation pulses. It is worth noting that the optimization approaches outlined above are even more essential for inversion pulses, as the Fourier transform does not predict the existence of z magnetization, and would therefore appear to be particularly useless as a tool for predicting pulse shapes for inversion. Indeed, we see in Figure 6 how the response of a 180° sinc pulse has little relation to its Fourier transform behavior, and does not seem to be a particularly effective pulse for inversion. In contrast, using the optimization techniques mentioned previously the inversion problem becomes quite simple. It is an easier problem than in-phase excitation because we have to optimize only one component of the magnetization rather than two. Most of the references cited above for excitation also treat inversion, and Figure 6 shows a selection of responses to increasingly sophisticated inversion pulses. Note that in addition to functions that were discussed for excitation, the Hermite pulse¹² is a simple analytical shape with one variable parameter that performs well for inversion.

Figure 6 A comparison of the (simulated) $\langle I_z \rangle$ response (vertical axis) as a function of offset from the carrier frequency for a rectangular pulse, a 180° Gaussian, a 180° sinc, an I-BURP Fourier series pulse,²³ and a G^3 Gaussian pulse cascade.²²

4 GENERAL ROTATIONS

The selective pulses described above were designed by optimizing the response of a spin whose initial state is proportional to $\hat{I}_z$ and is subsequently converted into a transverse operator, for example $\hat{I}_x$, or is converted into $-\hat{I}_z$. However, in many instances pulses are required to convert transverse components into longitudinal ones (for example in

soft-COSY), or in the case of refocusing the pulse should produce a 180° rotation in the transverse plane. There is a subtle but important difference between a pulse that was optimized to produce a particular *transformation* and a pulse that was optimized to produce a particular *rotation*. It may be tempting to assume that a pulse that converts $\hat{I}_z$ into $\hat{I}_x$ would also necessarily convert $\hat{I}_x$ into $-\hat{I}_z$. This is not in general true, as there are an infinity of rotations that will produce the transformation. For example, either a 90° rotation around the y axis, or a 180° rotation about an axis inclined at 45° in the xz plane achieves the first transformation. A 90° rotation around the y axis will indeed also convert $\hat{I}_x$ into $-\hat{I}_z$, but a 180° rotation about an axis inclined at 45° in the xz plane achieves the opposite result, converting $\hat{I}_x$ into $+\hat{I}_z$.

In order to find a pulse which selectively achieves the pure rotation one must produce a so-called ‘general rotation’ or ‘universal pulse’.^{23,24} These are pulses which are tailored to produce a particular rotation (normally 90° or 180°) about a fixed axis (normally in the transverse plane). Two approaches have so far been adopted in the optimization of general rotation pulses. The first utilizes symmetry properties of selective pulses, as it has been shown that a time-symmetric amplitude modulated pulse with phase γ is constrained to produce a rotation in the yz plane.^{30,31} Thus, if a time-symmetric pulse achieves the transformation of $\hat{I}_z$ into $\hat{I}_x$ it must correspond to a rotation of 90° about the y axis. The same logic applies to 180° rotations. Geen and Freeman²³ have constrained Fourier series pulses to be time symmetric and produced general rotation pulses in this way. The second approach relies on an optimization of the rotation matrix, or propagator, of the pulse directly. This approach has the advantage that the pulse need not be time symmetric, and in this way Emsley and Bodenhausen²⁴ have produced asymmetric Gaussian pulse cascades for general rotations. The pulses were produced by optimizing the elements of a quaternion representation of the propagator,^{30,32,33} which can be simply related to the rotation axis and flip angle of the pulse.²⁴

5 OTHER SELECTIVE PULSES

Selective pulses which are produced for excitation and inversion of a single spin $I = \frac{1}{2}$ are by far the most common. There are, however, a few variations that have been developed for other purposes. The most common variation is undoubtedly modulation of a given inversion or excitation pulse so as to produce multiple inversions or excitation. The principle is simply that modulation of the time domain pulse by a function $\exp\{-i\omega_{\text{mod}}t\}$ shifts the region of excitation or inversion by a distance ω_{mod} away from the carrier frequency in the frequency domain (this simple result is predicted by the convolution theorem of the Fourier transform). The addition theorem of the Fourier transform tells us that if we add several time domain functions, the result in the frequency domain is the addition of the individual responses. Therefore addition of pulses with different modulation frequencies should produce excitation or inversion at those different frequencies. Although we have seen that the Fourier transform is not valid to predict nonlinear responses, the addition theorem still holds for NMR excitation, and multiply-selective manipulations are indeed possible. The condition for validity is that the frequency difference between two adjacent affected regions should be

larger than the radiofrequency field strength of the individual pulse, $\Delta\omega_{\text{mod}} > \omega_1$. If this condition is not met, the field at one frequency will interfere with the effect of the field at another, and the responses will be spoiled.

Multiply-selective excitation by frequency modulation is an old idea which is commonly used in MRI experiments to select multiple slices through an object. It has only recently, however, become a popular tool in high-resolution experiments since it has been shown that it is often useful to irradiate two coupled spins simultaneously. This is simply achieved by modulation of the pulse shape with a cosine function which produces two symmetrically disposed sidebands at $\pm$ the modulation frequency. The related article by Bodenhausen, *Selective Hartmann–Hahn Transfer in Liquids*, treats these experiments in more detail. One should note, however, that when pulses are applied simultaneously to two (or more) coupled spins the response is no longer the same as it would be for the individual spin case. The equation of motion governing the evolution of a two-spin system would be in a 15-dimensional basis space, instead of the three-dimensional space that governs the single spin. Indeed it has been recognized that multiply-selective irradiation can lead directly to the creation of multiple quantum coherences in coupled spin systems,^{34,35} although it is then difficult to control the offset dependence of the excitation.

At the time of writing the only shaped pulses that have been developed specifically to act on both partners in a coupled spin system are those of Lee et al.³⁶ for refocusing of the dipole–dipole interaction. The shape is described by an expansion in terms of Legendre polynomials,¹⁹ and the coefficients of the polynomials were optimized so that the leading error terms appear in the higher orders of an average Hamiltonian treatment (see *Average Hamiltonian Theory*). However, the application is not selective but on the contrary is designed to be broadband, with the far off-resonance behavior being of little consequence. Nevertheless it is interesting to note that shaped pulses are shown to be more power efficient in this application than rectangular pulses.

Another interesting development using selective pulses has recently been demonstrated for selective spin decoupling.^{37–39} In the approach of Eggenberger et al.³⁷ a selective inversion pulse (specifically a G^3 Gaussian pulse cascade²²) is used as the building block in a recursive decoupling scheme. The resulting multiple-selective pulse sequences are shown to be very effective at decoupling within a selected region, while they have no effect outside the decoupled region. These sequences are shown to be useful in multidimensional experiments on large molecules, where it is necessary to decouple, for example, carbonyl carbons, while leaving the aliphatic carbons untouched. One should note that as long as the initial condition of the spins to be decoupled is proportional to $\hat{I}_z$, the G^3 pulse is suitable (as it is specifically an inversion pulse), but that in general one should use 180° general rotation pulses in the recursive expansion to produce an isotropic sequence to decouple any initial condition.

Finally, we note that Warren and co-workers have developed selective pulses which are insensitive to the effects of radiation damping during the pulse, or similarly to the effects of transverse relaxation on the frequency domain profile of the response. The pulses were developed simply by extending the equations of motion of equation (2) to include the desired interference effect, and subsequently optimizing the pulse over

a range of different values for the interference term. (These results have been presented at conferences, but so far appear to be otherwise unpublished). Some selective pulses have been shown to be particularly sensitive to radiofrequency field inhomogeneity,²³ and it would be useful to find pulses which were less sensitive to this ever-present effect, although to date nobody appears to have done so.

6 BANDWIDTH–DURATION PRODUCTS

A selective pulse must fulfil several criteria before it can be judged ‘good’ or ‘bad’. As we mentioned in the Introduction, the pulse should have a good ‘shape selectivity’, and this quality can be measured as the size of the deviation of the frequency domain response from an ideal ‘top hat’. This is the quality that is used as the target function in the least-squares optimization of the pulses discussed above, and we have seen that in this respect pulses can be made nearly ideal. However, there is a price to pay for this high performance in shape selectivity, and that is in the ‘time efficiency’ of the pulse. A selective pulse should have a *bandwidth–duration product* that is as small as possible. It turns out that a useful way to quantify the width of a function is by the variance of the mean-squared modulus, which for a function $f(x)$ is given by^{6,40}

$$\Delta x^2 = \frac{\int x^2 |f(x)|^2 dx}{\int |f(x)|^2 dx} - \left(\frac{\int x |f(x)|^2 dx}{\int |f(x)|^2 dx} \right)^2 \quad (6)$$

where the integrals are all taken between infinite limits. While there are many possible definitions of a bandwidth–duration product, this definition has the advantage that it can be used in either domain, i.e., $x = \Omega$ or $x = t$, and that it can be shown that the product $\Delta t \Delta \Omega$ is constant. Thus for a given pulse shape we can calculate the width of the pulse and the width of the response independently of the actual duration of the pulse, and the value of $\Delta t \Delta \Omega$ for a given pulse/response combination therefore represents the time efficiency of the pulse. In Table 2 we give the bandwidth–duration products for the various pulses of Figures 1 and 5. The values are expressed in units of $1/(4\pi)$, as this is the theoretical minimum value permitted by the uncertainty condition in a linear response regime. In Figure 7 we show graphically how the change in bandwidth–duration product affects the selectivity of the pulse. Note that, in general, the better the shape selectivity, the worse the time efficiency. One of the few remaining challenges in the area of selective excitation is to find pulses that are both shape selective and time efficient.

7 NMR TECHNIQUES USING SOFT PULSES

There now exists a broad range of experiments which use selective pulses and we shall not review them in detail here. The simplest applications use selective pulses to increase resolution in multidimensional experiments so as to allow a quantitative determination of scalar coupling constants.^{41–43} Alternatively, resolution remains the same and the number of increments in the indirectly recorded dimension is reduced, thereby reducing the experimental time required to obtain a spectrum.^{41,42,44} In general experiments

Table 2 Bandwidth–Duration Products $\Delta t \Delta \Omega$

Pulse	90° sinc	90° Gaussian	270° Gaussian	E-BURP-2	SEEK-3	G^4
$\Delta t \Delta \Omega$	2.77	1.1	0.9	2.90	2.37	6.7

**Figure 7** A comparison of the bandwidth of the $\langle I_x \rangle$ response (vertical axis) for G^4 , SEEK-3, and 270° Gaussian pulses. All the pulses are 50 ms in duration. The horizontal axis spans ± 100 Hz from resonance

using selective pulses can be divided into two broad classes. The first are sequences which use selective pulses (often in combination with nonselective pulses) to reduce the dimensionality of experiments.^{45–56} The second contains sequences which use only selective pulses to record two-dimensional spectra,^{5,16,41–43,57–62} and which have been developed for assignment based on soft-COSY methods or selective TOCSY methods. Several three-dimensional techniques using selective pulses have been proposed,^{51,63–65} but until the time of writing these do not appear to have gained much popularity. Techniques based on double irradiation form a category on their own for both assignment and distance determination.^{34,54–56,61,62,66–70}

Finally, there also exist several different techniques for the determination of relaxation parameters,^{16,55,66,70–77} from a simple determination of transverse relaxation in coupled spin systems,⁷⁶ to a complete determination of the individual elements of the relaxation matrix.⁷⁵ (These experiments are considered in more detail in the articles *Selective NOESY* and *Selective Relaxation Techniques in Biological NMR*).

8 CONCLUSION

The development of sophisticated pulses for selective excitation and inversion has triggered an explosion in the development of techniques using selective manipulations. These techniques can aid at all stages in structure determination, from assignment to the determination of coupling constants and relaxation rates. The number of experiments, and their relative efficiency, are growing rapidly and are likely to become an indispensable tool in cases where a structure does not yield to routine nonselective approaches.

1 INTRODUCTION

NMR spectroscopists have traditionally used constant amplitude ('rectangular') radiofrequency pulses, for a variety of reasons. During a rectangular pulse, the Hamiltonian remains constant in the rotating frame. For uncoupled spin systems, this permits direct integration of the Bloch equations; the pulse generates a readily predicted rotation of the magnetization, and the spin vector follows a very simple trajectory. Even when a density matrix approach is needed, it is often true that couplings can be neglected during any individual pulse, and visualizing the effect of each individual pulse as a simple rotation dramatically simplifies the theoretical description of the effects of complex sequences. There were once technological reasons for the popularity of rectangular pulses as well: rapid development of digital technology in the 1960s and 1970s made it possible to generate quite complex 'data patterns' (and hence pulse sequences where the radiofrequency gate was either 'on' or 'off'). Finally, the very small voltages characteristic of NMR signals (many orders of magnitude weaker than the irradiating pulses) demanded techniques for producing excellent isolation between transmitter and receiver, and such isolation is far easier with switches that have only two states than with devices that produce an adjustable output voltage. Thus extremely sophisticated sequences of rectangular pulses are easily implemented on most commercial spectrometers, and have obviously been used successfully in an enormous variety of applications.

Even after 50 years of this development, however, some experiments remain fundamentally difficult, and applications to more complicated systems require additional technique development. The most common example of an NMR problem that is not easily solvable by a rectangular pulse sequence is selective excitation (see *Selective Pulses*) of a single transition or range of frequencies. Selectively exciting the spectral region of interest reduces data acquisition time and spectral complexity, especially in multidimensional experiments. Alternatively, for an experiment such as solvent suppression, one may wish to excite over a broad frequency range with the exception of a narrow frequency region or notch. As another example, the need for expensive high-power amplifiers to cover the large spectral width in solid state

experiments can lead to problems such as sample heating or probe arcing.

This article will focus on the uses of shaped pulses (including amplitude modulation and either phase or frequency modulation) to address these issues and others. Any conceivable waveform with a bandwidth comparable to the width of the NMR spectrum is readily synthesized today with inexpensive commercial components. Sequences of shaped pulses have been successfully used in a wide variety of experiments. Pulse shaping has been extensively applied to ensembles of two-level systems; common applications include clean selective inversion with reduced power dissipation, self-refocused selective excitation, and solvent suppression experiments. Shaped pulses are also routinely used in magnetic resonance imaging (MRI) (see *Magnetic Resonance Imaging: A Historical Overview*) to improve resolution and reduce power dissipation. Applications to coupled multilevel systems remain an active area of research today, but shaped pulse sequences have been used to replace complex multiple pulse sequences in applications with scalar-coupled spins, dipolar-coupled spins, and quadrupolar nuclei. This can overcome instrumental limitations and provide broader uniform excitation at reduced peak powers. In principle, it is virtually always possible to get reduced power dissipation, better resolution, or artifact reduction with non-rectangular pulses; the difficulty comes in trying to find the best pulse shape to use.

2 RECTANGULAR PULSE EFFECTS

The simplest and most straightforward method of selective excitation is to use a single, low-amplitude rectangular rf pulse of relatively long duration. Starting from z magnetization ($M_z = 1, M_x, M_y = 0$) the excitation after a rectangular pulse phased along the rotating frame x axis with peak Rabi frequency ω_1 , duration T (which is much shorter than any relaxation time in the system), and resonance offset $\Delta\omega$ ($\Delta\omega = \omega_0 - \omega$, where ω_0 is the resonance frequency and ω is the carrier frequency of the rf wave) can be calculated analytically (neglecting relaxation):¹

$$M_x(\omega_1, T, \Delta\omega) = 2M_0 \frac{\omega_1 \Delta\omega}{\Delta\omega^2 + \omega_1^2} \sin^2[\frac{1}{2}(\Delta\omega^2 + \omega_1^2)^{1/2}T] \quad (1)$$

$$M_y(\omega_1, T, \Delta\omega) = M_0 \frac{\omega_1}{(\Delta\omega^2 + \omega_1^2)^{1/2}} \sin[(\Delta\omega^2 + \omega_1^2)^{1/2}T] \quad (2)$$

$$M_z(\omega_1, T, \Delta\omega) = M_0 \{ \cos^2[\frac{1}{2}(\Delta\omega^2 + \omega_1^2)^{1/2}T] - \frac{\omega_1^2 - \Delta\omega^2}{\omega_1^2 + \Delta\omega^2} \sin^2[\frac{1}{2}(\Delta\omega^2 + \omega_1^2)^{1/2}T] \} \quad (3)$$

If the pulse is applied on resonance ($\Delta\omega = 0$), it generates a rotation about the x axis by an angle $\theta = \omega_1 T$, which is also universally known as the flip angle. A $\frac{1}{2}\pi$ pulse ($\theta = \frac{1}{2}\pi$) creates the maximum possible transverse magnetization; a π pulse generates complete inversion of the populations. This result is equivalent to that obtained through density matrix mechanics.

From equations (1)–(3), the excitation from a $\frac{1}{2}\pi$ or π pulse decreases substantially if $\Delta\omega \gtrsim \omega_1$. Lengthening the pulse while keeping θ constant decreases ω_1 , and hence increases the selectivity—as expected from the uncertainty

principle relation $\Delta\nu \Delta\tau \approx 1$ (the exact value depends on the pulse shape). However, the excitation is not uniform near resonance, and some excitation persists far outside the nominal bandwidth. This is easy to understand in the linear response limit, which corresponds to a very small flip angle; in that case, the transverse magnetization [equations (1) and (2)] reduces to the Fourier transform of the rectangular pulse itself. The discontinuities at the beginning and end of the pulse produce high-frequency components in the excitation, thus introducing excitation far outside the nominal bandwidth. Solvent suppression sequences, which aim to produce a broad and uniform excitation profile with a sharp 'hole' in the middle, encounter similar difficulties.

The excitation profile from a radiofrequency pulse clearly depends critically on the pulse shape, since changing the shape changes the magnitude of the frequency components; however, predicting pulse shape effects is generally far more complicated than simply Fourier transforming the waveform. For example, Fourier transform arguments predict that a $\sin(\alpha t)/t$ (sinc) pulse produces a rectangular excitation profile but this only works well if the pulse is very weak.² As shown in Figure 1, the excitation becomes highly distorted as the pulse area approaches π . Nonetheless, more sophisticated treatments show that Fourier arguments have their uses. For example, it is generally true that any waveform with edges will have trouble producing highly localized excitation. Thus, for example, sequences of back-to-back rectangular pulses (see **Composite Pulses**) have been extremely successful in compensating for many of the practical limitations of rectangular pulse trains; but each added pulse introduces more discontinuities into the excitation profile, and, as a result, the performance far from resonance is generally difficult to control.

Figure 1 (a) The Fourier transform of a $\sin(\alpha t)/t$, or sinc, pulse is a rectangle. This argument only works well to $\theta = 30^\circ$. (b) The inversion profile for a sinc π pulse. The deviations from linear response are quite substantial

3 GENERAL EFFECTS OF SHAPED PULSES

Pulse shaping provides a powerful means to circumvent the limitations of rectangular pulses. The effects of an arbitrarily phase- or amplitude-modulated pulse can be formally calculated by breaking up the pulse into a large number of small, nearly constant pieces and then either solving the Bloch equations or employing density matrix mechanics. For two-level systems, both methods are equivalent. In the laboratory frame, the radiofrequency pulse $\mathbf{B}_1(t)$ is generally produced along a single axis (which we shall call the x axis, with unit vector $\mathbf{i}$): $\mathbf{B}_1(t) = B_1(t)\mathbf{i}$. The Hamiltonian, which includes the effects of the static magnetic field $\mathbf{B}_0 = B_0\mathbf{k}$ (along the z axis, with unit vector $\mathbf{k}$) as well as this pulse, can be written as

$$\hat{\mathcal{H}}(t) = \hbar\gamma[B_0\mathbf{k} + B_1(t)\mathbf{i}] \cdot \hat{\mathbf{I}} = \hbar[\omega_0\hat{I}_z + \omega_1(t)\hat{I}_x] \quad (4)$$

An arbitrarily modulated pulse $\omega_1(t)$ can be described^{3,4} by a time-dependent amplitude $A(t)$ and phase $\vartheta(t)$:

$$\omega_1(t) = A(t) \text{Re}\{\exp[i\vartheta(t)]\}, \quad A(t) \geq 0 \quad (5)$$

where the total phase $\vartheta(t)$ is known modulo 2π . While Equation (5) is perfectly general, it is normally the case in NMR that only a small fractional bandwidth about some fixed carrier frequency ω is needed (for example, normal ^1H solution NMR spectra spread over 10 ppm = 10^{-5} of the center frequency) so it is more convenient to write

$$\omega_1(t) = A(t) \text{Re}\{\exp[i\omega t + \phi(t)]\} \quad (6)$$

If ω is correctly chosen, $\phi(t)$ varies far more slowly than does $\vartheta(t)$. We can then write

$$\begin{aligned} \omega_1(t) &= [A(t) \cos \phi(t)] \cos \omega t - [A(t) \sin \phi(t)] \sin \omega t \\ &\equiv \omega_{1x}(t) \cos \omega t - \omega_{1y}(t) \sin \omega t \end{aligned} \quad (7)$$

with the amplitude and phase modulation of the pulse reflected in $\omega_{1x}(t)$ and $\omega_{1y}(t)$. Changing the assumed carrier frequency ω changes the functions $\phi(t)$, $\omega_{1x}(t)$, and $\omega_{1y}(t)$. Transforming to a frame rotating at the carrier frequency ω gives the following Hamiltonian:

$$\hat{\mathcal{H}}(t) = \hbar[\Delta\omega\hat{I}_z + \omega_{1x}(t)\hat{I}_x + \omega_{1y}(t)\hat{I}_y] \quad (8)$$

In a density matrix picture, this rotating frame transformation is accomplished by the unitary operator

$$\hat{U} = \exp[-i\omega t \hat{I}_z] \quad (9)$$

This frame of reference is also known as the phase-modulated (PM) frame. In this frame, the instantaneous rotation generated by the pulse is about an axis in the direction $[\omega_{1x}(t), \omega_{1y}(t), \Delta\omega]$. The phase-modulated frame rotates at a constant frequency, and is thus equivalent to the usual NMR definition of rotating frame.

Alternatively, the pulse can be expressed by the time-dependent amplitude $A(t)$ and the instantaneous frequency $\omega_i(t)$. It is tempting, but *incorrect*, to write $\vartheta(t) = \omega_i(t)t$ and conclude that the instantaneous frequency is just the phase

divided by time. Instead, the instantaneous frequency $\omega_i(t)$ is properly defined as the time derivative of the total phase $\vartheta(t)$:

$$\omega_i(t) \equiv \dot{\vartheta}(t) = \omega + \dot{\phi}(t) \quad (10)$$

This perspective leads naturally to the frequency-modulated (FM) rotating frame, which at any instant in time is synchronous with the instantaneous pulse frequency $\omega_i(t)$. This rotating-frame transformation is accomplished by the unitary operator

$$\hat{U} = \exp\{-i[\omega t + \phi(t)]\hat{I}_z\} \quad (11)$$

In this frame, the Hamiltonian becomes

$$\hat{\mathcal{H}}(t) = \hbar[\omega_0 - \omega_i(t)]\hat{I}_z - A(t)\hat{I}_x \equiv \hbar[\Delta\omega(t)\hat{I}_z - A(t)\hat{I}_x] \quad (12)$$

where the instantaneous resonance offset $\Delta\omega(t) = \dot{\phi}(t)$ and the amplitude $A(t)$ dictate the direction of the rotation axis. Note that the y component has disappeared, at the expense of a time-varying z component; hence the PM and FM frames each have calculational advantages. At any instant in time, the PM and FM frames are related by a z axis rotation equal to the instantaneous phase $\phi(t) \equiv \arctan[\omega_{1y}(t), \omega_{1x}(t)]$ that explicitly depends on the choice of carrier frequency ω .

For example, consider an amplitude- and phase-modulated Gaussian pulse envelope⁵

$$\omega_1(t) = C \exp[-(at)^2] \exp[i(\omega t + bt^2)] \quad (13)$$

with carrier frequency ω , pulse amplitude $A(t) = C \exp[-(at)^2]$, and time-varying phase function $\vartheta(t) = \omega t + bt^2$. The instantaneous frequency is given by equation (10) as

$$\omega_i(t) = \omega + 2bt \quad (14)$$

not $\omega + bt$, as would be found if $\vartheta(t) = \omega_i(t)t$. For this pulse, $\omega_i(t)$ varies linearly with time; the pulse is said to be ‘chirped’.

Some general properties of shaped pulses are well known. A purely amplitude-modulated pulse on resonance generates a rotation determined by the flip angle of the pulse, just as for the rectangular case. Therefore, we can generate the desired rotation by adjusting either the peak amplitude or pulse duration. However, off-resonance effects cannot be generalized from rectangular pulse behavior, because the peak Rabi frequency, ω_1 , is not constant. The variation in the direction of the rotation axis or size of the rotation angle with changing $\Delta\omega$ or ω_1 is not calculable analytically, except for a very few special cases.

The effects of phase-modulated or frequency-modulated pulses cannot be extrapolated from rectangular pulse solutions. The concept of flip angle is not valid for phase-modulated or frequency-modulated pulses.^{6,7} One important special case of frequency modulation is adiabatic inversion: if the frequency $\omega(t)$ is swept very slowly through the spectral range of interest (from far below resonance to far above resonance), the magnetization vector will be completely inverted from M_z to $-M_z$ as long as the pulse amplitude exceeds a certain level. Even if the amplitude is increased further, the pulse is effectively a π pulse. The phase-modulated pulse envelope $\omega_1(t) = (\text{sech } \alpha T)^{1+\mu}$ with $\mu = 5$ has been shown to perform such an adiabatic inversion with the added benefit

of a rectangular inversion profile.³ This pulse can also be viewed as a frequency-swept pulse with amplitude $A(t) = \text{sech } \alpha T$, phase $\phi(t) = \mu \ln(\text{sech } \alpha T)$ and instantaneous frequency $\omega_i(t) = \mu\alpha \tanh(\alpha T)$. Silver et al.⁸ showed that the even if the peak amplitude is increased by a factor of 10, the $(\text{sech } \alpha T)^{1+5}$ pulse remains a π pulse, whereas the flip angle of a rectangular pulse would have increased to 10π . This means that frequency-modulated pulses can compensate for effects such as rf inhomogeneity, which presents some obvious advantages; for example, the sample can be larger than the coil volume but still be inverted uniformly. However, a frequency-modulated pulse is difficult to use as an echo pulse (see *Spin Echo Spectroscopy of Liquid Samples*), because the apparent rotation axis changes as the amplitude increases. For this reason, purely amplitude-modulated pulses are usually the best choice to replace rectangular π pulses in existing sequences.

4 PULSE SHAPING IN TWO-LEVEL SYSTEMS

Pulse shaping theory for unrelaxed and uncoupled two-level systems has been extensively developed. The response of a spin system to any shaped pulse can always be exactly calculated by breaking the pulse into a large number of small rectangles. However, the inverse problem, determining what pulse shape to use to achieve a desired response, is the real problem of interest and is not easily solvable. Theoretical progress towards solving this problem comes from three somewhat different but complementary directions: closed form solutions for specific pulse shapes, perturbative or exact expansions for describing the effects of arbitrary pulse shape, and computerized optimization.

Closed-form solutions for specific pulse shapes are most valuable for the insight they provide. Unfortunately, the exact effects of any arbitrarily shaped pulse on the magnetization are not known analytically. In fact, analytic solutions exist for only two other waveforms besides the rectangular pulse case: a $(\text{sech } \alpha T)^{1+\mu}$ pulse with arbitrary α and μ (equivalently, a sech pulse envelope with a tanh frequency sweep)⁴ and an exponential envelope pulse.^{9,10} Furthermore, a rectangular pulse is the only one that can be solved for all initial conditions, all resonance offsets, and all amplitudes. In practice, most of the commonly used pulse shapes were found by numerical methods.

Several different approximate approaches have been used to describe the behavior of arbitrarily shaped pulses. Approximate solutions are useful because they provide physical insight: they tell us why a particular shape behaves as it does and suggest directions for improvement. For example, the frequency response produced by a pulse can be approximated using Fourier arguments, as previously described. These predictions from linear response theory are accurate in the limit where the pulse area is small. Other treatments that give some physical insight include perturbative expansions of the magnetization and perturbative expansions of the effective Hamiltonian.⁴ Formalisms such as inverse scattering^{11,12} or Floquet operators^{13,14} have been used to produce analytic expressions for the inversion profile from an arbitrary pulse shape. More recently, Shinnar and Leigh¹⁵ have developed a ‘direct synthesis’ technique for the numerical inversion of the Bloch equations. In many of these cases, the theoretical

treatment is nearly exact in certain limits, and may be extrapolated to cover a wider range of experimental conditions. The key difference between these treatments generally has to do with the range over which they adequately approximate the exact solutions, which can always be obtained (numerically) by breaking the pulse into many rectangular pieces.

Because the number of analytic solutions is quite limited, virtually all of the truly useful waveforms have been generated by computerized optimization. Optimization starts by defining the following elements: the functional form of the pulse shape, the method of calculating the spin response for a defined spectral range, and the quality factor Q for the pulse shape, which quantifies deviations from the idealized target profile (for example, the root-mean-square deviation from a profile that reflects complete inversion over some bandwidth and no effect outside that bandwidth). These parameters must be carefully defined, because, even for a simple pulse shape, it is impossible to explore the entire range of parameter space. The pulse shape is systematically varied as the quality factor is assessed, until the desired response is achieved. Optimization algorithms range from conjugate gradient routines¹⁶ to more sophisticated schemes¹⁷ such as evolutionary methods,²⁷ simulated annealing, and neural networks. Each method has its own advantages and disadvantages, depending on the need to find a local or a global minimum.

An optimized shaped pulse can easily be created for most applications involving two-level systems, ignoring the effects of relaxation, coupling, and radiation damping. Many different optimization schemes have been used to create useful shapes.¹⁸ For example, computerized optimization in two-level systems has produced shaped pulses for clean selective inversion with reduced power dissipation;¹⁹ self-refocused selective excitation (including compensation for phase roll),²⁰ and solvent suppression.^{21,22} This approach allows us to calculate numerically the effects of any pulse shape. Unfortunately, it gives little insight into why a particular shape would work well. Therefore, computerized optimization is most effective when used in combination with an approximate solution.

4.1 Tradeoffs

In two-level systems, many different pulses produce the same or nearly the same inversion profile. There is no ‘best’ pulse shape. The best pulse for any specific application is

determined by experimental details such as the need for uniform excitation versus the need for localized effect or the narrowest possible bandwidth. In general, there are tradeoffs between pulse complexity, peak power, total applied energy, and phase distortions far from resonance. The significance of these tradeoffs is different for different applications. For example, a more complicated pulse can be used for selective excitation to give sharper edges in the ‘transition region’ between complete inversion and no effect at the expense of increased power dissipation or pulse length. The importance of these tradeoffs is illustrated in Table 1, which examines the inversion profiles of four amplitude modulated pulses shown in Figure 2 at the same peak power.

Ideally, there would be 100% excitation over the bandwidth of interest (frequency selectivity) and no excitation outside this range (no side lobes). Rectangular pulses excite the broadest range of frequencies but only a small region is completely inverted and low amplitude side lobes lead to unwanted excitation far from resonance. Gaussian pulses^{23,24} eliminate the long frequency tails produced by rectangular pulses, at the expense of somewhat increased pulse length and smaller completely inverted region. Also, Gaussian pulses produce a broad region of excitation that is too large to be neglected but does not reach 100%. These “semiselective” pulses have been used quite extensively (see, e.g., Kessler et al.²⁵), perhaps because of the simplicity of the waveform, but in fact current technology allows for the generation of much more sophisticated waveforms with equal ease. A Hermite pulse²⁶ (a polynomial multiplying a Gaussian) has a much larger completely excited bandwidth for the same peak power. At the opposite extreme, the asymmetric pulse shape^{4,27} provides a vastly larger completely excited bandwidth, but it is substantially longer. This longer pulse could present a problem if extremely narrowband excitation is desired; the pulse length could then become comparable to relaxation times.

4.2 Phase Roll

There is one important problem with many of the shaped pulses described above. Because they are relatively long, they induce a strong variation in the phase of the excited signal across the selected region. This can be described physically as a spreading out of spin isochromats that are experiencing different effective fields. In the simple example of a long

Table 1 Comparison of Amplitude-Modulated Pulse Shapes (Reproduced by Permission of John Wiley & Sons from S. McDonald and W. S. Warren, *Concepts Magn. Reson.*, 1991, 3, 55)

Shape	Length (peak power ω_1)	Completely inverted region ^a	Bandwidth (fwhm)	Completely uninverted region ^b
Rectangular pulse [Figure 2(a)]	$1.0T (= \pi/\omega_1)$	$< \pm 0.09\omega_1$	$\pm 0.8\omega_1$	$> \pm 1.1\omega_1$
Gaussian pulse [Figure 2(b)]	$2.0T^c$	$< \pm 0.06\omega_1$	$\pm 0.63\omega_1$	$> \pm 1.6\omega_1$
Hermite pulse [Figure 2(c)]	$4.8T^c$	$< \pm 0.15\omega_1$	$\pm 0.55\omega_1$	$> \pm 1.5\omega_1$
Asymmetric pulse [Figure 2(d)]	$8.0T$	$< \pm 0.45\omega_1$	$\pm 0.77\omega_1$	$> \pm 1.05\omega_1$

^aWithin this frequency range, magnetization starting at $+I_z$ ends up within 10° of $-I_z$.

^bOutside of this frequency range, magnetization starting at $+I_z$ ends up within 10° of $+I_z$.

^cThese pulse shapes are assumed to be truncated at 5% of peak amplitude.

Figure 2 Various amplitude-modulated π pulses at the same peak power (left-hand plots) and the responses to them (right-hand plots): (a) square pulse; (b) Gaussian pulse; (c) Hermite pulse; (d) asymmetric pulses. (Reproduced by permission of John Wiley & Sons from S. McDonald and W. S. Warren, *Concepts Magn. Reson.*, 1991, **3**, 55)

rectangular pulse of duration T , phase roll originates from the delay of $\frac{1}{2}T$ between the pulse center (since the Fourier transform of the pulse is only real if this point is chosen as $T = 0$) and the end of the pulse when detection is possible. Phase rolls are not detected in routine spectra of liquids because the short intense $\frac{1}{2}\pi$ or π pulses making $\Delta\omega T$ small for the entire spectrum. If the lines are narrow and resolved, conventional NMR processing software routines can be used to correct a linear phase variation. This is much harder (and sometimes impossible) if peaks overlap; compensating for phase roll becomes a much more difficult task. In some cases, refocusing can be achieved by applying a hard π pulse after the shaped pulse, but customized shaped pulse schemes are more efficient at eliminating phase roll. This has been accomplished with amplitude-modulated $\frac{3}{2}\pi$ pulses and with phase- and amplitude-modulated pulses.^{20,28}

5 PULSE SHAPING IN MULTILEVEL SPIN SYSTEMS

Most of the advanced experiments in NMR cannot be adequately described by a distribution of uncoupled and unrelaxed two-level systems, and pulse shapes derived in this context have severe limits in their applicability. Shaped pulse sequences designed for two-level systems cannot be successfully extended to applications of multilevel spin systems when pulse lengths become comparable to the reciprocal of a typical coupling. For example, shaped pulses developed for double selective inversion experiments do not work well in the presence of scalar couplings owing to the creation of double quantum coherence.³¹ Amplitude-modulated waveforms optimized for narrowband inversion of uncoupled spins encounter similar difficulties when applied to dipolar-coupled spins.³⁰

Several groups have shown that it is possible to devise sequences of shaped pulses that compensate for the effects of couplings, relaxation or radiation damping. This represents the frontier of the current understanding of pulse shape generation, and optimal waveforms are still evolving. Multilevel systems present the same ‘inverse’ problem as did two-level systems—usually the desired spin response is known, and an appropriate irradiation scheme is desired. Because the Bloch equations cannot be used to establish the effects of a shaped pulse on multilevel spin systems, density matrix mechanics must be employed. The time evolution of the density operator $\hat{\rho}(t)$ of a spin system under a time-dependent Hamiltonian $\hat{\mathcal{H}}(t)$ can be determined from the Liouville–von Neumann equation

$$\frac{d\hat{\rho}(t)}{dt} = -i[\hat{\mathcal{H}}(t), \hat{\rho}(t)] \quad (15)$$

For a time-independent Hamiltonian, equation (15) integrates to

$$\hat{\rho}(t) = \hat{U}(t)\hat{\rho}(0)\hat{U}^{-1}(t) \quad (16)$$

where $\hat{U}(t)$ is the propagator, defined as

$$\hat{U}(t) = \exp(-i\hat{\mathcal{H}}t) \quad (17)$$

The effects of any pulse on a two-level system can be completely characterized by calculating the propagator $\hat{U}(\Delta\omega)$

while scanning the single parameter of resonance offset. The situation becomes far more complicated in multilevel spin systems. N coupled spins generate a $2^N \times 2^N$ Hamiltonian, and, even in favorable cases (such as molecules dissolved in liquid crystal solvents, where only a few spins have measurable couplings), the size of these matrices guarantees that calculations will be exceedingly slow. The extent of these calculations makes brute force optimization impractical for coupled spin systems. In addition, one finds empirically that local minima in the quality factor are abundant in these problems, and it is very difficult to use gradients (changes in the quality factor from small changes in the pulse shape) to produce dramatic improvements. But if these were the only problems, supercomputers and ever-faster workstations would provide a straightforward solution. The real challenge is to find pulse shapes that will be *robust*—they have to be usable without knowing in advance every possible detail of the Hamiltonian, and they must be insensitive to rf inhomogeneity and the exact magnitude of coupling matrix elements. Building such robustness into a normal optimization is extraordinarily difficult. A two-level system has only one parameter in its internal Hamiltonian (the resonance offset), and the effects of a pulse shape might be calculated for 100 resonance offsets at each stage of the optimization. In the next simplest case (two coupled spins A and B), the Hamiltonian in general has two chemical shifts $\Delta\omega_a$ and $\Delta\omega_b$, plus coupling J_{ab} :

$$\hat{\mathcal{H}} = \Delta\omega_a \hat{I}_{az} + \Delta\omega_b \hat{I}_{bz} + 2\pi J_{ab} \hat{I}_a \cdot \hat{I}_b \quad (18)$$

But then an optimization with equivalent frequency resolution would require $(100)^3$ calculations at each stage, or else a new waveform would be needed for every possible molecule! Even if fewer J values were examined, the size of the calculation would still increase dramatically. For networks of coupled spins, this method is hopeless.

A more promising approach is to combine computerized optimization with other techniques to restrict the searches to a more meaningful range. For example, average Hamiltonian theory and predictions based on symmetry considerations can be used to constrain a search to sequences that are more likely to be robust and can produce simple and useful pulse shapes.

5.1 Average Hamiltonian Theory and Symmetry Considerations

Average Hamiltonian theory is an alternative approach to calculating the exact Hamiltonian during a pulse sequence (see *Average Hamiltonian Theory*). The propagator $\hat{U}_{\text{int}}(t)$ corresponding to the time-dependent internal Hamiltonian $\hat{\mathcal{H}}_{\text{int}}(t)$ is defined as

$$\hat{U}_{\text{int}}(t) = \hat{\mathcal{T}} \exp \left[-i \int_0^t \hat{\mathcal{H}}_{\text{int}}(t) dt \right] \quad (19)$$

where $\hat{\mathcal{T}}$ is the Dyson time ordering operator. If the exponential is expanded and terms of equal order are collected, the propagator becomes

$$\hat{U}(t) = \exp(-it \hat{\bar{\mathcal{H}}}) \quad (20)$$

with

$$\hat{\mathcal{H}}(t) = \sum_{k=0}^{\infty} \hat{\mathcal{H}}^k(t) \quad (21)$$

This is known as the Magnus expansion.³² The effective Hamiltonian is still in the time-dependent or toggling frame. If the Hamiltonian is periodic with period t_c ,

$$\hat{\mathcal{H}}(t + nt_c) = \hat{\mathcal{H}}(t) \quad (22)$$

and if the system is only observed at multiples of the cycle time, then the propagator $\hat{U}(t_c)$ expressed in terms of the average Hamiltonian $\hat{\mathcal{H}}(t)$ predicts the time evolution of the system.

Predictions can be made by symmetry considerations (based on average Hamiltonian theory), which are applicable to any spin system and help reduce the vastly increased degrees of freedom associated with optimizing sequences of shaped pulses. For example, the basic decoupling pulse sequence R should not just be repeated to perform decoupling for a long interval; it will perform better in this application if it is phase-shifted and permuted into the configuration (RRRR), where the pulse $\bar{R}$ is the mirror image of R, phase shifted by 180° (obtained by time-reversing the order of the individual pulses and rotating by π about the z axis).²⁹ Any rf field applied antisymmetrically in time,

$$\hat{\mathcal{H}}_{\text{rf}}(t_c - t) = -\hat{\mathcal{H}}_{\text{rf}}(t) \quad (23)$$

produces a symmetric $\hat{\mathcal{H}}_{\text{int}}$.³³ If $\hat{\mathcal{H}}_{\text{int}}$ is symmetric in time,

$$\hat{\mathcal{H}}_{\text{int}}(t - t_c) = \hat{\mathcal{H}}_{\text{int}}(t) \quad (24)$$

and all odd-order terms in the Magnus expansion vanish. This property has been used extensively for designing sequences for selective averaging of unwanted operator terms in the Hamiltonian. In general, this implies that one can either use symmetric pulse shapes in the sequence, or asymmetric pulse shapes in the first half of the sequence with their mirror images in the second half. The propagator for these backward pulses (mirror images) is closely related to the propagators for the forward pulses. Therefore, a pulse shape need not be constrained to be symmetric, and this greatly reduces computation time.

5.2 Optimization of Pulse Shapes

It does not make sense to ‘start from scratch’ in an optimization for a multilevel system, particularly for an experiment that has been extensively analyzed for rectangular pulses. A more productive approach is to embed the pulse shape into a pulse sequence framework that already has some desirable properties. For example, one of the first coupled spin experiments to be optimized using shaped pulses was dipolar time reversal or double quantum excitation,³⁴ an experiment notoriously sensitive to experimental imperfections. To simplify the optimization, Lee et al.³⁴ started with the simplest two-quantum sequence, the two-pulse sequence shown in Figure 3(a). In addition, this sequence consists of purely amplitude-modulated pulses, which further restricts the calculation.

A straightforward method for amplitude modulation is to divide the pulse into N points, either in the time or frequency domain, and vary each point subject to the constraints

$$|\omega_1(t)| \leq \omega_{1,\text{peak}} \quad (25)$$

$$\int_0^{t_p} \omega_1(t) dt = \theta \quad (26)$$

where θ is the total area of the pulse. For this experiment, $\theta = \frac{1}{2}\pi$. Because these optimizations can be time-consuming, it is useful to keep the number of free parameters to be varied to a minimum while exploring all reasonable pulse shapes. However, a low-resolution approximation will produce pulses with crude shapes; furthermore, because each point is still rectangular, discontinuities at the edges can erode some of the advantages of pulse shaping. One approach to overcome these limitations is to expand the pulse in terms of some basis function that can be systematically varied. This has the advantage of ensuring that the pulse envelope contains no discontinuities or steep edges at the beginning or end of the pulse. For the two-quantum dipole sequences, the pulse shape was expressed as a series of Legendre polynomials,³⁴ and then the coefficients of the polynomials were optimized so that

the leading error terms appear in $\hat{\mathcal{H}}^{(2)}$. An effective shaped pulse sequence [Figure 3(b)] was generated with only three polynomials. In other applications, a finite Fourier series³⁵ was used as the basis for expansion. This expansion is useful, because limiting the contribution from higher-order terms in the series discourages the introduction of more convoluted shapes.

Another approach for parameterizing the pulse shape is based on spline interpolations.³⁶ The shaped pulse is defined by a relatively small number n of variable relative amplitudes a_i at variable relative time points t_i , and then a cubic spline interpolation is used to approximate the pulse shape as N rectangular subpulses k with amplitudes A^k and durations t_k . This procedure produces smooth shapes that can have rapid amplitude changes. Also, the number of maxima and minima in the pulse shape is limited by the n ‘anchor points’ (a typical value of n is 10). By comparison with the basis function parameterization, which gives rise to global changes in the shape as coefficients are varied, this method is local in the sense that the shape changes only in the region of the varied parameter.

Figure 3 (a) The simplest pulse sequence for generating dipolar time reversal. (b) Amplitude-modulated shaped pulse sequence optimized to generate a two-quantum effective Hamiltonian

5.3 Applications

These principles have been used to produce shaped pulse sequences that show improved performance in applications with scalar-coupled spin systems, dipolar-coupled spin systems, and quadrupolar nuclei. Optimizations that were restricted to a system of two coupled spins produced shapes that are useful for networks of coupled spin systems. The resultant shaped pulse sequence for dipolar time reversal, as shown in Figure 3(b), has been experimentally demonstrated to work for benzene molecules in a liquid crystal with as many as 64 energy levels.³⁴ (The energy level structure was not included in the optimization.) The shaped pulse sequence operates well with a peak power that is more than an order of magnitude less than the rectangular pulse experiments. In another application, shaped pulses designed for narrowband inversion of dipolar-coupled spin pairs³⁰ show a degree of selectivity for the coupling strength that may prove useful for imaging order in liquid crystals and polymers.

In high-resolution NMR, complicated multiple pulse sequences can be replaced with shaped pulses optimized for multilevel spin systems. This has been demonstrated in homonuclear decoupling experiments. The most effective but experimentally demanding mechanism of homonuclear coherence transfer is isotropic mixing, used in total correlation spectroscopy or TOCSY (see **TOCSY in ROESY and ROESY in TOCSY**). Isotropic mixing allows in principle for efficient coherence transfer between all spins belonging to the same coupling network, even if spins are separated by multiple bonds. This contributes significant new information by giving rise to additional cross peaks from indirectly coupled spins that can help assign long-chain amino acids in proteins and confirm ambiguous assignments made by other methods. TOCSY uses an extended mixing period during which a suitably chosen pulse sequence suppresses chemical shift terms, leaving an effective Hamiltonian with only isotropic scalar coupling terms ($\hat{H}_m = \sum_{k < l} 2\pi J_{kl} \hat{I}_k \hat{I}_l$). A good mixing sequence allows efficient coherence transfer over a wide offset range. This is limited by the amount of available rf power and by sample heating problems associated with extended mixing sequences of high-power pulses. Thus, the TOCSY experiment is a good candidate for pulse shape optimization.

An amplitude-modulated shaped pulses sequence optimized for TOCSY has been shown³⁷ to outperform the conventional decoupling sequences, such as MLEV-16,³⁸ WALTZ-16,³⁹ and DIPSI-2,⁴⁰ especially at low peak powers. In addition, pulse shaping forms the basis for a chemical-shift-selective version of TOCSY. In tailored correlation spectroscopy or TACS_Y,⁴¹ shaped pulses can accomplish efficient coherence transfer over a range of chemical shifts (e.g., in the aliphatic region of ¹³C) without affecting a specified region (e.g., carbonyl resonances). Current progress in the optimization of sequences for isotropic mixing involves minimizing the effects of cross relaxation, which can decrease the amplitude of desired cross peaks. The effects are suppressed by clean TOCSY sequences which have been created by modifications to existing sequences⁴² and computer optimization.⁴³

6 CONCLUSIONS

Pulse shaping provides an extra degree of freedom for designing pulse sequences that has been shown to be useful

in a wide variety of experimental contexts. By combining exact solutions, approximate methods, and computerized optimization, it is conceivable to create an optimized shaped pulse sequence that gives the desired spin response for most applications. Sequences of shaped pulses have overcome many 'instrumental' constraints such as peak excitation power, heating effects, and bandwidth considerations. In multilevel applications, complex multipulse sequences can be profitably replaced with simple shaped pulses.

1 INTRODUCTION

Spectral editing techniques in NMR in general are methods that aid the spectroscopist in assigning or simplifying complex high-resolution spectra. Most approaches to spectral editing have been developed in the context of NMR of ^{13}C where the emphasis has been on separating ^{13}C resonances on the basis of their multiplicity, i.e. the number of directly attached ^1H s. This type of information, when combined with the analysis of ^{13}C chemical shifts, is very often sufficient for determining the chemical structure of rather complex organic molecules. As such, spectral editing of solution NMR finds wide application in industry for the structural characterization of polymers, drugs, and petroleum based products. Development of similar methods which are applicable to solid samples has been motivated by a large number of important applications to geochemical and material science.

This article deals with spectral editing approaches developed specifically for high-resolution solid state NMR of ^{13}C . Many different strategies have been applied to this problem, and the space provided here unfortunately does not permit covering every aspect of this subfield. Most of the relevant literature is cited in two recent papers,^{1,2} and the interested reader may find more extensive citations contained therein.

2 BACKGROUND ON SPECTRAL EDITING OF LIQUIDS

The high information content of ^{13}C NMR spectra of liquids is well known. It follows directly from the large dispersion of the ^{13}C chemical shift and the remarkably tight correlation of ^{13}C chemical shifts with structure. The beautiful stick-spectrum simplicity of ^{13}C spectra is made possible by ^1H decoupling and the low natural abundance of ^{13}C which eliminates complications from ^{13}C – ^{13}C J couplings. Their information content is greatly increased if the multiplicity of the ^{13}C resonances can be determined.

Editing techniques for ^{13}C NMR of liquids rely on the fairly narrow range of values for $^1J(^{13}\text{C},^1\text{H})$. This permits one to devise pulse sequences in which the evolution of the ^{13}C magnetization can be made to depend principally upon the number n of directly attached ^1H s in CH_n groups. The attached proton test (APT) is the simplest example. In its most basic form, a $\pi/2$, τ , π , τ , acquire echo sequence is applied to the ^{13}C with ^1H decoupling during acquisition. A π pulse is also applied to the ^1H s after the first τ , resulting in J modulation of the ^{13}C spin echo. During the 2τ evolution period the dephasings of the ^{13}C chemical shifts are refocused, while those due to $^1J(^{13}\text{C},^1\text{H})$ accumulate. Setting τ to $\frac{1}{2}J$ produces a spectrum in which the CH_3 and CH_1 resonances are inverted, while the CH_2 and CH_0 resonances are absorptive.

For complex ^{13}C spectra, more powerful methods are required, but all rely upon J couplings in some manner. In editing protocols based on INEPT, J modulation is used to label the ^1H magnetization which is then transferred to the ^{13}C (see *INEPT*). The various CH_n groups can be amplitude modulated in distinct ways depending upon the length of the time evolution due to J coupling. On this basis schemes can be devised in which linear combinations of a few different experiments produce CH_3 -only, CH_2 -only, CH_1 -only, and CH_0 -only spectra. Techniques utilizing DEPT provide some improvement in selectivity, as the differentiation of CH_n groups depends upon a pulse flip angle rather than a period τ of free evolution under $^1J(^{13}\text{C},^1\text{H})$. Especially clean separation of CH_n subspectra has been achieved using multiple quantum coherence among the J -coupled spins. This subspectral editing using a multiple-quantum trap (SEMUT) has the advantage of being relatively insensitive to the value of $^1J(^{13}\text{C},^1\text{H})$.

3 CHALLENGES POSED BY SOLIDS

As discussed elsewhere in the Encyclopedia, obtaining high-resolution ^{13}C spectra of organic solids requires both magic angle spinning (MAS) and high-power decoupling of the protons. These techniques are usually combined with cross polarization (CP) in a CP MAS experiment. The need to remove broadening associated with chemical shift anisotropy and ^{13}C – ^1H dipolar couplings presents a new set of problems in the design of methods for spectral editing. Over the last 20 years of development in high-resolution NMR of solids three basic strategies have been applied to this problem. The first has been to design pulse sequences which produce J -modulated signals in solids, and thereby directly adapt the techniques just discussed to solids. The others use ^{13}C – ^1H dipolar couplings as the basis for selection of CH_n . Some of these methods use the relative strengths of dipolar couplings or rates of CP to differentiate ^{13}C signals of different multiplicities. Others rely upon the establishment of quasi-equilibrium states in the CP process and thus differentiate the ^{13}C multiplicities on the basis of the ratio of the inverse rotating frame spin temperature of the ^{13}C to that for its directly bonded protons.

3.1 J Modulation in Solids

Observing resolved $^1J(^{13}\text{C},^1\text{H})$ -coupled multiplets in CP MAS ^{13}C spectra of solids is made difficult by the strong

^1H – ^1H and ^1H – ^{13}C dipolar couplings. In the absence of strong on-resonance ^1H decoupling, CP MAS spectra of typical rigid samples are broad and relatively featureless. The ^1H – ^{13}C dipolar broadening is by itself inhomogeneous, and should therefore be suppressed by MAS. However the spin-exchange mediated by the ^1H – ^1H dipolar couplings is faster than typical rates of MAS. Therefore the spin states of ^1H can change several times during a MAS cycle, and the average of the ^1H – ^{13}C dipolar interaction is then no longer zero. In a simplified picture one can consider this to be a lifetime broadening of the ^{13}C resonances due to the short lifetime of the spin states of the directly attached protons. Terao and co-workers³ first demonstrated that suppression of the ^1H – ^1H dipolar couplings could make it possible to observe $^1J(^{13}\text{C},^1\text{H})$ -coupled multiplets in solids. In their work, ^1H decoupling at the magic angle in the rotating frame was first used. Subsequently a number of homonuclear sequences such as MREV-8 have been applied as homonuclear multiple pulse decoupling (MPD) for this purpose. For systems such as plastic crystals where molecular motion has already appreciably averaged the dipolar couplings, MPD produces CP MAS spectra with well-resolved $^1J(^{13}\text{C},^1\text{H})$ coupled multiplets. The couplings observed are reduced by the scaling factor appropriate to the particular MPD sequence used.

This approach has been extended to editing schemes that most resemble those used in liquids. The basic approach is to insert MPD sequences in the periods of free evolution under $^1J(^{13}\text{C},^1\text{H})$. APT-type spectra of motionally narrowed solids have been acquired in this fashion, but in the general case the MPD does not produce sufficient narrowing of the proton NMR spectra to permit sustained J modulation. Terao and co-workers⁴ have investigated the limitations of this approach most extensively for rigid solids. One sequence they have successfully used in producing J modulation for rigid solids consists of CP followed by a J -modulated rotor synchronized echo. During the first half of the echo, magnetization of the ^{13}C nuclei evolves under proton homonuclear decoupling. This period, t_1 , is adjusted to be equal to one rotor cycle. Over the course of the rotor period J modulation accumulates, but any modulation by the ^{13}C – ^1H dipolar coupling and the ^{13}C CSA is refocused. After the π pulse, high-power dipolar decoupling is applied for another period t_1 . This second interval refocuses the isotropic chemical shift and effects of any bulk susceptibility broadening that accumulated during the first t_1 period. FIDs taken as a function of t_1 then are largely only modulated by $^1J(^{13}\text{C},^1\text{H})$. In this manner a 2D heteronuclear J -resolved spectrum can be obtained with multiplets in the ω_1 dimension. However this approach still does not yield clean multiplets. For instance, the outer lines in quartets for CH_3 groups are very much broader than the central pair, and they are barely resolved.

At the moment, J modulation based editing techniques for solids will remain useful only for systems with significant motional narrowing. Advances in the efficiency of homonuclear decoupling, especially under conditions of MAS, are needed before such techniques can become widely applicable. Problems also remain in combining these homonuclear decoupling requirements with the typical hardware used for CP MAS NMR. While the approach has been proven in principle, development of generally applicable methods for solids along these lines remains a challenge for the future.

3.2 Dipolar Dephasing and Related Schemes

The most generally applicable editing techniques for solids take advantage of the strong dipolar couplings inherent in solids, rather than treating them as a nuisance to be eliminated. The simplest approach to spectral editing in CP MAS NMR of organic solids is the venerable technique⁵ of dipolar dephasing (DD) or interrupted decoupling. After CP, the ^1H decoupler is turned off for $\sim 50\ \mu\text{s}$. This is a sufficient time for the ^{13}C – ^1H dipolar coupling to dephase the transverse magnetization for any ^{13}C with a directly bonded ^1H , as long as the dipolar coupling is not motionally averaged. Therefore the lines for rigid CH_1 and CH_2 groups are effectively suppressed. Rapid rotation of CH_3 groups at room temperature leads to different behavior for these protonated carbons. This rotation renders the three ^{13}C – ^1H dipolar couplings equal, and reduces them to one-third of their static value. Depending upon the spin state of the protons, the ^{13}C in a CH_3 group can experience one of two possible dipolar fields. Whenever the three protons are in the same state ($\alpha\alpha\alpha$ or $\beta\beta\beta$), the three couplings reinforce one another, and the ^{13}C experiences the field of a single full ^{13}C – ^1H dipolar coupling. However, three-quarters of the time the ^1H s are in a state such as $\alpha\alpha\beta$ or $\beta\beta\alpha$. In this instance the fields due to two of the couplings will exactly cancel. The net dipolar field then is usually only one-third of a single ^{13}C – ^1H dipolar coupling, and this is similar to that often experienced through nonbonded contacts by a CH_0 . Thus, in most instances, methyl groups at room temperature behave like nonprotonated carbons under dipolar dephasing. The DD spectrum then consists of slightly attenuated resonances for just the CH_0 and CH_3 groups. Comparison with a fully polarized CP MAS spectrum provides a simple qualitative method for categorizing resonances as either $\text{CH}_3 + \text{CH}_0$ or $\text{CH}_2 + \text{CH}_1$. In many instances, a simple CP MAS spectrum can be fully assigned using this approach in combination with information from linewidth or chemical shifts.

Several approaches have been taken to improve on the basic DD technique. In some instances the dephasing interval leads to an unacceptable linear phase correction due to the delayed acquisition. A π pulse may be inserted in the interrupted decoupling interval to alleviate this to some degree. However, as first pointed out by Munowitz and Griffin,⁶ the π pulse should be applied only after a full rotor period to ensure that both the isotropic and anisotropic portions of the ^{13}C chemical shift are refocused. Other groups have investigated the spin dynamics of the DD experiment with the desire to separate CH_n resonances more completely or quantitatively.⁷ The approach has been to fit the dephasing of the ^{13}C resonances as a function of the dephasing time, τ_D , to some type of model dephasing function. Since it can be argued the different CH_n groups may have characteristic dephasing characteristics, this approach would seem to have some validity. In this manner one can then extrapolate back in dephasing time to recover the initial intensities of the CH_3 and CH_0 resonances.

The best way to view the DD experiment is actually as a low-resolution 1D version of separated local field (SLF) spectroscopy under MAS conditions. During τ_D the ^{13}C FID is dominated by the ^{13}C – ^1H dipolar couplings, and is damped by the ^1H – ^1H dipolar interactions. An isolated CH_1 group then has a decay profile that is essentially a damped Pake doublet FID, that for a CH_2 , i.e. a Pake ‘triplet’. Since the local structure of isolated CH_n groups of a given n does not

vary appreciably in organic solids, these decays would be quite characteristic were it not for the ^1H – ^1H dipolar couplings. This complication can be removed by applying MPD during the dephasing interval. In this manner the number of dipolar couplings is determined from a spectral pattern, i.e. sideband intensities, rather than from a less structure-specific average dephasing rate.

The first proposal for this type of MAS SLF spectroscopy was by Munowitz and Griffin⁶ as a means of measuring C–H distances. Webb and the author⁸ later investigated using the spinning sideband patterns characteristic of the different CH_n groups for spectral editing. The proposed 2D experiment consists of CP followed by MPD (usually MREV-8) for t_1 to produce dipolar evolution in the first frequency dimension. This is followed by a $\pi/2(\phi_i)$, τ , $\pi/2(x)$ sequence to selectively project the ^{13}C magnetization onto one axis of the rotating frame. The period, τ , is a few hundred μs and is used to dephase magnetization not placed along z by the $\pi/2(\phi_i)$ pulse. Following the $\pi/2(x)$ pulse, the normal dipolar decoupled ^{13}C FID is acquired during time period t_2 . Cycling the phase ϕ_i in a time proportional phase incrementation scheme avoids the need to acquire a quadrature data set in t_1 . The sideband patterns generated this way in the ω_1 dimension retain both dipolar and CSA effects. However, at low-to-moderate field strengths the patterns are so dominated by the ^{13}C – ^1H dipolar couplings that they can still be easily deconvolved into their CH_n components. Since CH_2 groups have two dipolar couplings, they have nearly twice as many sidebands, and are readily distinguished from CH_1 groups by this technique. Decomposition of complex CP MAS spectra with many overlapping lines has been demonstrated using this approach. At higher fields the same deconvolution methods can be applied using Munowitz and Griffin's rotor-synchronized sequence to eliminate the complications due to CSA. The requirement for delaying acquisition to several rotor periods after the initial CP interval, however, can result in substantial losses in sensitivity. A further simplification has been proposed by Sethi.⁹ Since the temporal evolution during t_1 in the MAS SLF experiments is well understood, only a few special times t_1 need be acquired. Using this approach Sethi has introduced 1D editing schemes that also can be used to separate CH_1 and CH_2 resonances.

3.3 Schemes Using CP Dynamics

The previous methods rely upon the relative strengths of ^{13}C – ^1H dipolar couplings or the different numbers of dipolar couplings to discriminate between different CH_n groups. The dipolar couplings are used essentially to dephase or modulate the ^{13}C resonances in a predictable manner. Another strategy is to use the ways in which these differences in the dipolar coupling network result in differences in the CP dynamics between the CH_n groups.

The simplest description of the CP process considers the transfer as a first-order kinetic process with a time constant T_{CH} . However, it is well known that this description is only qualitatively correct, and only phenomenologically describes the long-time behavior ($t \gg T_2$). At short CP times the Hartmann–Hahn transfer is dominated by the details of the dipolar coupling network between a ^{13}C and its directly bonded ^1H s. In single crystals, one even observes transient

oscillations in the polarization transfer. For powdered samples under moderate MAS, the transient effect manifests itself as a rapid initial period of CP transfer in which the ^{13}C and its attached ^1H s come into a quasi-equilibrium. Spin diffusion to the more distant protons transports polarization more slowly to these ^1H s coupled to the ^{13}C . This slower process determines the rate at which the ^{13}C reaches its final fully polarized state. In the quasi-equilibrium state, the initially unpolarized ^{13}C nuclei share the polarization equally with their directly attached protons. CH_1 and CH_2 groups then polarize to one-half and two-thirds of their full intensity, respectively, on the short timescale. Because of their motionally averaged dipolar field, CH_3 groups behave similarly to nonprotonated carbons. Both the CH_0 and CH_3 groups then polarize more slowly, with the polarization bottleneck to full enhancement usually being the rate of ^1H – ^1H spin diffusion. As long as the transfer of transient polarization among the closely coupled spins is faster than the ^1H – ^1H spin diffusion and direct transfer from more distant protons, it can be put to good use in spectral editing schemes.

One particularly useful approach for distinguishing the signals of $\text{CH}_1 + \text{CH}_2$ from those of $\text{CH}_0 + \text{CH}_3$ based on the previous ideas is the depolarization (DEP) technique.¹⁰ After a several ms CP interval, the spin locked ^1H magnetization is allowed to dephase by turning off the ^1H rf for several hundred μs , while keeping the ^{13}C spin locked. Turning the ^1H rf back on reestablishes the CP contact, and the ^{13}C magnetization can be used to repolarize the depolarized ^1H s. If the phase of the ^1H rf is switched 90° every 25–50 μs over a total period of a few hundred μs , there will be no net buildup in the ^1H magnetization, only a net drain from the ^{13}C . Since only the $\text{CH}_1 + \text{CH}_2$ carbons polarize on this timescale, their signals are fully depleted after the depolarization, while the $\text{CH}_0 + \text{CH}_3$ signals are attenuated only slightly. The resulting DEP spectrum is much like a DD spectrum. However since the ^{13}C are spin locked until the depolarization is finished, there are no problems with linear phase errors as in DD.

Polarization inversion (PI) can also be used in a similar fashion.¹¹ In this technique the ^{13}C are first fully polarized by CP, and the phase of the rf in the ^1H channel suddenly inverted. Since the ^1H spin temperature has now been inverted, the ^{13}C will try to follow. Those ^{13}C with strong ^{13}C – ^1H dipolar couplings first quickly depolarize, and then repolarize in the opposite direction. Since the zero crossings for CH_1 and CH_2 groups are different, they can be used in some instances to distinguish resonances. Nulling of resonances in this manner has also been referred to as cross depolarization¹² (CPD). A further variant adds a final short polarization period onto the CPD sequence.¹³ The depolarization and repolarization periods in this cross-depolarization–repolarization technique (CPDR) can be adjusted so as simultaneously to null the CH_1 and CH_2 groups. This is not in general possible with the cross-depolarization interval alone.

Sangill et al.² have presented a thorough study of the use of CPD and CPDR in spectral editing. Their analysis focused on using optimized combinations of CPD and CPDR spectra to produce CH_n -only spectra, $n = 0$ –3, while maintaining good sensitivity. By paying careful attention to the CP dynamics, they were able successfully to separate complex CP MAS spectra into their CH_n subspectral components.

Burum and Bielecki¹⁴ have introduced a particularly clever method based on CP dynamics for selectively detecting CH_2

groups in CP MAS NMR. Their method, WIMSE (windowless isotropic mixing for spectral editing), starts with a CP interval under a multiple pulse cycle which eliminates the ^1H – ^1H dipolar couplings during the CP step while maintaining the ^{13}C – ^1H couplings. Over a MAS rotor period under these conditions, no net polarization is transferred to ^{13}C nuclei in CH groups. Instead, whatever magnetization is transferred at the start of the rotor cycle ‘echoes’ back from the ^{13}C to the ^1H at the end. However, the presence of two dipolar couplings in a CH_2 group defeats this ‘rotational polarization echo’ effect. The resulting spectrum then consists solely of the CH_2 component in a complex CP MAS spectrum. CH_3 and CH_0 lines do not appear as their CP rates are too slow.

3.4 Techniques Using Quasi-Equilibrium States

Another successful method based on differences in CP dynamics between the different CH_n groups is the solid state attached proton test, or SSAPT method. Initially the ^{13}C are fully polarized using a 2–3 ms CP interval. Immediately following this, a short PI period is applied, typically on the order of $50\ \mu\text{s}$. At the beginning of the PI time the ^{13}C and their directly attached ^1H s are equally polarized. Upon reversal of the phase in the ^1H spin locking rf, this equilibrium is broken, and the spins try to reequilibrate. Since the CH_3 and CH_0 groups polarize slowly, they are relatively unaffected by this short PI interval. The CH_2 and CH_1 groups, on the other hand, have sufficient time to reach a quasi-equilibrium state through a rapid transient CP transfer. In the case of the CH_1 group, the ^{13}C and the ^1H have equal but opposite polarizations at the start of the PI. During the short PI time these magnetizations cancel, and the signal for the CH_1 carbons is very effectively nulled. The ^{13}C nuclei in the CH_2 groups carry 1 unit of polarization as opposed to the -2 units in the ^1H s at the beginning of the PI interval. This results in -1 unit of total polarization to be shared among the three spins in the quasi-equilibrium state. At the end of the PI period, the CH_2 signal is then inverted with an intensity of $-\frac{1}{3}$ of its fully polarized signal. The SSAPT spectrum then has $\text{CH}_3 + \text{CH}_0$ signals nearly fully polarized and positive, CH signals nulled, and CH_2 signals inverted at one-third intensity. In many instances this provides a very straightforward means of separating the contributions from the different CH_n groups to a ^{13}C CP MAS spectrum.^{15,16}

This approach has been extended to a complete spectral editing protocol by Wu, Burns, and the author.¹ Since the establishment of the quasi-equilibrium state depends upon the ratio of the inverse rotating frame spin temperatures of the ^{13}C and its directly bonded ^1H s, this technique is less sensitive to the CP rates. In this sense it is a relatively robust editing procedure.

The complete spectral editing procedure due to Wu et al. uses four basic experiments (see Figure 1). One begins by acquiring a CH_2 -only spectrum. The sequence used starts with a short CP contact which polarizes the CH and CH_2 groups to their quasi-equilibrium intensities of $\frac{1}{2}$ and $\frac{2}{3}$ respectively. This is followed by a short PI interval of roughly the same length. During PI the CH signals null, as does any small CH_3 or CH_0 polarization built up during the CP step. The CH_2 ^{13}C magnetization goes to $-\frac{1}{3}$ of its initial value, resulting in a spectrum with $-\frac{2}{9}$ the intensity for these carbons. This

Figure 1 Sequences used in the editing protocol of Wu et al. All employ simultaneous phase inversion to alleviate problems with Hartmann–Hahn mismatches. (a) CP sequence. The additional spin locking delay $\tau_{\text{SL}}^{\text{S}}$ is used to make the total ^{13}C spin locking time the same in all of the sequences. (b) SCPPI sequence used to acquire CH_2 -only spectra. (c) Depolarization sequence. The time $\tau_{\text{SL}}^{\text{I}}$ is added in these sequences mainly to minimize distortions from ^1H rotating frame relaxation

short CP polarization inversion (SCPPI) spectrum then has contributions from only the CH_2 groups.

The second experiment is a short contact CP (SCP). This will have intensity principally from the CH and CH_2 carbons. Another short CP spectrum with a depolarization interval is also acquired (SCPD). The SCPD spectrum can be used to subtract out the contamination of the SCP data from CH_3 and CH_0 groups. Unfortunately the CH_3 and CH_0 carbons have sufficiently different CP dynamics that they are differentially attenuated, and this subtraction alone is insufficient. In most instances, however, the shift ranges for CH_3 and CH_0 groups are adequately separated so that a dividing line on the ^{13}C chemical shift scale can be chosen to separate these groups. Different weighting factors can then be applied to the upfield (CH_3) and downfield (CH_0) regions for this purpose. The result of this procedure is a relatively clean CH-only spectrum.

To acquire semiquantitatively correct CH_0 and CH_3 spectra, a long CP depolarization spectrum is acquired (LCPD). This spectrum is again split into CH_0 and CH_3 regions, and each part corrected for the differential signal loss of the two types of groups in the depolarization step.

The cleanest and most quantitative results are obtained with this method if the intensity factors for spectral decomposition are determined experimentally on a known model system.

Table 1 Typical Intensities for CH_n Resonances in Pulse Sequences Used for Spectral Editing

Experiment	CH_n			
	CH_0	CH_1	CH_2	CH_3
LCP	100	100	100	100
SCP	10.5	57.5	68	22.6
SCPPI	0	0	-22	0
SCPD	7.2	0	0	10.4
LCPD	82.5	0	0	57.5

Using the set of sequences shown in Figure 1, the intensity matrix in Table 1 is found to be typical. LCP is used to denote a standard (long) CP experiment which is used as the 100% intensity reference.

As the entries demonstrate, the CH and CH_2 group intensities in the SCPPI and SCP experiments are quite close to those expected from the quasi-equilibrium description of the CP dynamics.

Figure 2 compares the four spectra acquired in the editing protocol for cholesteryl acetate to the normal CP MAS spectrum. In the solid state there are two molecules in the unit cell producing a doubling of the lines. Furthermore, changes in conformation lead to significant shifts in many resonances. Using the intensity matrix in Table 1, the CH_n , $n = 0-3$, only spectra can be reconstructed from these data. The results of this data manipulation are shown in Figure 3, clearly demonstrating the simplifications made possible by this spectral editing approach. As a check on this editing protocol, one may sum the CH_n subspectra to produce a synthetic CP MAS spectrum. This is compared with the normal CP MAS

**Figure 3** Subspectra constructed from the data in Figure 2. (a) Normal CP MAS spectrum again for comparison. (b) CH_0 -only. (c) CH_1 -only. (d) CH_2 -only. (e) CH_3 -only. Some of the assignments made possible by the editing technique are given in the inset**Figure 2** Data from a spectral editing experiment on cholesteryl acetate. (a) Normal CP spectrum for comparison. (b) SCP spectrum. (c) SCPPI spectrum. (d) SCPD spectrum. (e) LCPD spectrum. In practice larger numbers of scans are acquired for the lower signal-to-noise experiments as indicated in the figure

spectrum in Figure 4, along with the difference of the two. The small differences observed indicate the reliability of the approach used.

4 EXPERIMENTAL CONSIDERATIONS AND CAVEATS

Except for the simplest approaches to spectral editing in solids, one must pay some extra attention to the experimental setup. In particular, very high MAS spin rates and rf inhomogeneity can adversely affect the CP dynamics relied upon in most methods. The sharpening of the Hartmann-Hahn condition, and the need to match typically on a sideband condition, $\omega_1 = \omega_2 + \omega_r$, makes a homogeneous rf field more important than in a standard CP MAS experiment. Good experimental practice requires stable rf levels, restricting the sample to well within the rf coil, and a stable spin rate. For experiments utilizing short CP, PI, or depolarization periods, additional modifications that make the matching condition less sensitive are needed. Our group has found the simultaneous phase inversion method^{1,14,15} easy to incorporate in editing schemes. The pulse sequences in Figure 1 utilize this approach to make the results much less sensitive to how well the matching condition is set and maintained throughout the experiment.

Figure 4 Comparison of the (a) normal CP MAS spectrum and (b) the synthetic one produced by direct summation of the subspectra in Figure 3(b)–(e). (c) The difference between the normal and synthetic CP MAS spectra

When spectra are to be combined in an editing procedure, it is also important to consider rf heating, droop in the rf levels, and $T_{1\rho}$ relaxation. Whenever possible, it is a good practice then to keep the rf fields on for comparable periods of time in the different experiments to be combined. The sequences in Figure 1 have been constructed to take these additional complications into account. Table 2 gives the set of delays in reference to Figure 1 that have been found to give optimal performance in editing applications on rigid solids at moderate fields and MAS rates. These parameters have been used and tested in applications to many coals and polymers as well as on model systems.

Methods which employ homonuclear decoupling sequences require additional care in spectrometer alignment. For these methods one must more carefully adjust all rf levels, and pay especial attention to rf homogeneity. In practice one must follow the same procedures as used to prepare for a ^1H CRAMPS experiment. Similar complications from the interaction of the MAS and the MPD also occur as found in CRAMPS.

The majority of the methods that have been discussed here rely on differences in the dipolar coupling networks found between the various CH_n groups. These are washed out when there is significant motional averaging, and as such

all of these methods have limitations. On the other hand, such motional narrowing has many signatures which are easy to recognize, and provides another means of discriminating between resonances in a complex spectrum. When very fast MAS rates are employed, the spin dynamics also change.¹⁷ Most methods presented here work best at low to moderate MAS rates (5 kHz or below). Additional complications can arise at high fields because of the CSA spinning sidebands. Since different molecular orientations with respect to the rotor contribute more intensity to some sidebands than others, the inhomogeneous nature of the CP dynamics can be accentuated. Under many editing schemes the center and sidebands can then behave differently, complicating analysis. In the light of these difficulties, most applications to complex systems have employed low field operation ($B_0 < 4\text{ T}$). Additional work is needed to delineate how high-field and high-speed MAS operation can be accommodated with the majority of these methods.

5 SUMMARY

At present there are many methods available for distinguishing $\text{CH}_3 + \text{CH}_0$ groups from CH and CH_2 centers in CP MAS spectra. A number of reliable approaches for separating CH and CH_2 groups have also appeared, and some of these have been combined in complete spectral editing protocols which separate resonances by multiplicity. These methods have many applications in organic geochemistry and polymer science. Further advances are required before most of these techniques can be combined with operation at the highest available field strengths and spin rates.

Acknowledgments

I wish to acknowledge the especially important contributions of two of my colleagues in this field. The first is Dr Gretchen Webb, my first graduate student, who was instrumental in working out 2D MAS SLF methods for editing, as well as developing much of the hardware that

still makes these experiments work so well in our laboratory. The second is Dr Xiaoling Wu, my long-time associate, collaborator, and friend. It is because of Xiaoling's experimental acumen and theoretical insight that our laboratory has been able to contribute so successfully to the development of spectral editing methods for solids.

1 INTRODUCTION

Stochastic excitation is used for heteronuclear broadband decoupling in liquid state NMR and as a way to acquire spectra. This article is devoted to the second topic, which is known by the name of stochastic NMR spectroscopy.

1.1 Early History

The use of stochastic excitation in NMR has been a topic of continuous interest since the late 1950s. The idea of exploring noise in NMR goes back to two sources.

1. In Switzerland, Hans Primas was intrigued by the Wiener theory of nonlinear systems¹ and its consequences for NMR in the context of hole burning. The subsequent investigations of quantum mechanical systems with a stochastic Hamiltonian eventually led to the Habilitation work of Primas^{2,3} and to the Dissertation work of Richard Ernst.⁴
2. In the USA, noise was mentioned among other forms of excitation in a patent by Russel Varian relating to ways of improving the relative frequency stability of NMR spectrometers as well as the signal-to-noise ratio of NMR spectra.⁵ In 1966 stochastic excitation was put to practical use as a method for heteronuclear decoupling in high-resolution NMR.⁶

After the introduction of Fourier transform (FT) NMR in 1966,⁷ methods were sought that would keep the multiplex advantage of FT NMR but in addition would allow independent adjustment of sensitivity and resolution. It was Richard Ernst who pointed out that this could be achieved by using stochastic excitation,⁸ and he, as well as Reinhold Kaiser, published the first experimental stochastic NMR spectra in subsequent papers of the same issue of the *Journal of Magnetic Resonance* in 1970.^{9,10}

1.2 Noise

The type of noise most suitable for excitation in NMR is still being discussed. Many variants are conceivable:

binary noise, which can assume two values with equal probability quaternary noise, which can assume four values with different probabilities, and noise with a Gaussian probability distribution, to name but a few. These types of noise can be used to modulate the rf excitation in amplitude or in phase or in both parameters. Most experiments so far have used binary and quaternary white noise excitation either as pure amplitude or as four-valued phase modulation. To complicate the choice, the question of what white means can readily be answered for excitation of the linear response by the shape of the first-order autocorrelation function or its Fourier transform, the power spectral density. Ideally, the power spectral density should be a constant differing from zero and extending from minus infinity to plus infinity for white noise. But as soon as the response becomes nonlinear, higher order autocorrelation functions of the excitation need to be investigated.¹¹ On the other hand, the noise may deliberately be colored for selective excitation or suppression of particular frequency regions. This was demonstrated by Tomlinson and Hill in 1973.¹²

1.3 Linear Response

A particularly suitable type of noise for excitation of the linear response was investigated independently by Ziessow^{13,14} and Kaiser:¹⁵ If so-called *m*-sequences or maximum length binary sequences are used for excitation, the discrete power spectrum of the excitation is constant, just like that of a delta function pulse. This is remarkable insofar as the power spectrum of ordinary zero-mean white noise is again a noise signal. Only its mean value differs from zero, but its variance is as great as its mean. Increasing the length of such a noise sample will not change the variance of the power spectrum—only the spectral resolution will change.¹⁶ This is a manifestation of the well-known fact that the Fourier transform of white noise is an inconsistent estimate of the power spectral density. Therefore, ordinary stochastic NMR spectra are always contaminated by systematic noise.¹⁷ When *m*-sequences are used, this is not the case, and the NMR spectrum can be calculated by successive applications of the Hadamard transformation and the Fourier transformation. For this reason, this type of stochastic NMR is known as Hadamard NMR. In general, the linear response is processed to conventional 1D spectra, unless, in the presence of magnetic field gradients, it is processed to a projection of the object.¹⁸

1.4 Nonlinear Response

With the introduction of two-dimensional NMR in 1976, it was clear that similar spectra should also be obtainable with stochastic excitation. How this can be done eventually became my dissertation with Dieter Ziessow in Berlin.¹⁹ This work has been reviewed on a number of occasions.^{20–22}

The theoretical treatment of stochastic excitation was complicated by the requirement of solving stochastic differential equations,^{9,23} and eventually Reinhold Kaiser and the mathematician Bill Knight succeeded in providing solutions, which showed the correct power dependence of stochastic NMR spectra.^{24,25} These studies were later refined in the context of NMR imaging with stochastic excitation.^{26,27}

1.5 The Use of Stochastic Excitation

Up to now, stochastic excitation has not become a widely accepted technique in magnetic resonance for various reasons. One objection is a seemingly complicated theory. We are used to the vector representation of pulsed NMR, and the use of correlation integrals requires additional training. But more severe objections are that the manifold of tailored experiments is rather limited, and that most stochastic NMR spectra are contaminated by systematic noise. The dramatic power saving that stochastic excitation provides seems to be of little interest for most NMR applications. This is not so, however, for NMR imaging at high fields^{28–30} and for investigations of large objects by EPR,³¹ NMR, and NQR. In addition, novel types of non-white-noise excitations such as a time-shifted sum excitation (see below) can provide improved signal-to-noise ratios at known low power levels.^{31,32} Therefore, a valid interest beyond pure scientific curiosity remains. But, though the enthusiastically envisioned general applicability of the technique has not come to pass, its investigation in NMR provides detailed insight into nonlinear incoherent spectroscopy (NOISY), which has interesting potential for realizations of 2D spectroscopy in the optical frequency regime by interferometric techniques.³²

In the following discussion, the principles of stochastic excitation will be summarized, experimental examples will be given, and topics of current research will be addressed.

2 EXCITATION AND RESPONSE

Figure 1 illustrates what typical excitation and response signals look like.⁹ In this case, the excitation $x(t)$ (top) is binary noise, i.e., a signal that fluctuates at random between two values. In practice, these two values are assigned to flip angles $+\alpha$ and $-\alpha$ of a string of closely spaced rf excitation pulses. One pulse is applied at the beginning of each sampling interval, and, right before the next pulse, one value of the response $y(t)$ (bottom) is sampled. Thus, there is a one-to-one correspondence between excitation and response values. The use of pulses for excitation and the principle of time sharing

Figure 1 Binary excitation sequence $x(t)$ (a) and the corresponding stochastic response $y(t)$ (b) of the ^{19}F resonance of 40 vol% 2,4-difluorotoluene at a frequency of 56.4 MHz.⁹

between excitation and response are similar to FT NMR, but the durations of excitation and response, extending in principle from minus to plus infinity, are similar to continuous wave (CW) NMR. But, for practical reasons, time sharing is restricted to spectral widths smaller than about 100 kHz. For larger spectral widths, schemes that permit simultaneous detection of excitation and response, like the use of magnetic field modulation¹⁰ and crossed transmitter and receiver coils must be considered.

The formal description of stochastic NMR is based on the Volterra and Wiener theories, which describe the relationship between excitation and response of nonlinear systems in general.³³ The system to be characterized is represented by a 'black box', which transforms an input signal into an output signal. Because the system is unknown, a perturbation expansion is followed, which applies to the general input for the Volterra approach and to Gaussian white noise for the Wiener approach. The shortcoming of the Volterra approach is the perturbative treatment, because the NMR response often is highly nonlinear [see Figure 2(a)] and the convergence of the perturbation analysis breaks down at high excitation levels.

Figure 2 (a) Saturation of the transverse magnetization (signal RMS) as a function of the excitation level, demonstrating the nonlinearity of the response as a function of the excitation amplitude. (b) Simulated single pulse response spectra (FT, top) and stochastic 1D spectra for different excitation levels α_{RMS} , denoting the RMS flip angle of the excitation pulses with a white Gaussian distribution

2.1 The Volterra Series

The general system response $y(t)$ is expanded in a series of increasing powers of the excitation $x(t)$.³⁴ Because physical systems have memory, integrals over the memory times have to be incorporated. This results in the Volterra series

$$\begin{aligned} y(t) = & k_0 + \int_{-\infty}^{\infty} k_1(\tau)x(t-\tau) d\tau \\ & + \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} k_2(\tau_1, \tau_2)x(t-\tau_1)x(t-\tau_2) d\tau_1 d\tau_2 \\ & + \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} k_3(\tau_1, \tau_2, \tau_3)x(t-\tau_1)x(t-\tau_2) \\ & \times x(t-\tau_3) d\tau_1 d\tau_2 d\tau_3 + \dots \end{aligned} \quad (1)$$

The second term in equation (1) is a linear convolution integral, and the higher order terms are nonlinear convolution integrals of kernel functions $k_n(\tau_1, \dots, \tau_n)$ with the n th-order product of the excitation at times $t - \tau_i$, where $1 \leq i \leq n$. These kernel functions are memory functions that correlate n events at times τ_i in the past, and they are characteristic of the system under investigation. Thus, the goal in characterizing the system is to determine these memory functions.

The first term, k_0 , is just a dc (direct current) term, which can be neglected in practice. Then, for a linear system, only the second term is relevant. Here, $k_1(\tau)$ or its Fourier transform, $K_1(\omega)$, are readily determined by the familiar excitation signals from NMR. In CW NMR, the excitation $x(t) = x_0 \exp(i\omega t)$ is a continuous wave, so that $K_1(\omega)$ is measured directly. Thus, $K_1(\omega)$ is equivalent to the conventional 1D NMR spectrum. In 1D FT NMR, the excitation $x(t) = x_0 \delta(t)$ is a delta function pulse, giving $k_1(t)$. Thus, $k_1(t)$ corresponds to an FID signal. Correspondingly, $k_n(\tau_1, \dots, \tau_n)$ is the Fourier transform of an n D NMR spectrum. With respect to NMR, the odd orders of equation (1) apply to transverse magnetization and the even orders to longitudinal magnetization. Thus, in most cases, only odd-order terms need be considered—in particular, the linear and cubic terms.

2.2 The Wiener Series

The Volterra series in equation (1) was adapted by Wiener for zero-mean Gaussian white noise excitation.¹ With the original goal in mind of describing the system response with improving accuracy by incorporation of higher order terms, it is advantageous to orthogonalize the Volterra functionals. Then, neglecting even-order terms, the Wiener series can be derived from the Volterra series:

$$\begin{aligned} y(t) = & \int_{-\infty}^{\infty} h_1(\tau)x(t-\tau) d\tau \\ & + \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} h_{3s}(\tau_1, \tau_2, \tau_3)x(t-\tau_1)x(t-\tau_2) \\ & \times x(t-\tau_3) d\tau_1 d\tau_2 d\tau_3 \\ & - 3\mu_2 \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} h_{3s}(\tau_1, \tau_2, \tau_2)x(t-\tau_1)d\tau_2 d\tau_1 + \dots \end{aligned} \quad (2)$$

Here, the second moment μ_2 , or the power of the noise excitation, appears.

The leading terms of the Wiener and Volterra series are similar. For the Wiener kernels, the symbol $h_{ns}(\tau_1, \dots, \tau_n)$ has been used for discrimination from the Volterra kernels

$k_n(\tau_1, \dots, \tau_n)$, because as a result of the orthogonalization the kernels become dependent on the excitation power, and their Fourier transforms exhibit changes in linewidths and amplitude [Figure 2(b)], which are similar to saturation features observed in CW NMR, except, that they are also observed in multidimensional stochastic spectra.¹⁹ Also, an additional index s for ‘symmetric’ has been attached to the Wiener kernels, because they are often taken to be invariant under permutation of time arguments. This is mathematically convenient, but it violates the principle of causality, which becomes evident when the kernels are analyzed in terms of quantum mechanics (see below).

3 CROSS CORRELATION

The way to arrive at NMR spectra in stochastic NMR is by comparison of excitation and response records. Mathematically, a comparison is achieved by cross correlation, because the amplitude of the cross-correlation function is high, whenever the cross-correlated signals are similar. Because one is dealing with nonlinear response signals, nonlinear cross-correlation functions become of interest. The cross correlation of order n produces an n -dimensional function

$$\begin{aligned} c_n(\sigma_1, \dots, \sigma_n) = & \lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^T y(t)x^*(t-\sigma_1) \dots x^*(t-\sigma_n) dt \\ = & n! \mu_2^n h_n(\sigma_1, \dots, \sigma_n) \end{aligned} \quad (3)$$

where $*$ denotes the complex conjugate. The cross correlation function is defined in a time–displacement space, where the displacements σ_n count from the present t into the past (see Figure 3). Interestingly, as long as none of the time arguments are equal, the second equality holds, and the cross-correlation function is proportional to the Wiener kernel.³⁵

For acquisition of the stochastic response in NMR, the multiplex advantage applies, similarly to pulsed FT NMR.³⁶ But in multidimensional pulsed FT NMR, it applies to only one dimension, because the indirectly detected dimensions are scanned in a pointwise fashion. For the nonlinear Wiener kernels and their Fourier transforms, it applies to all dimensions in principle, because complete kernels can be calculated from a single record of input and output data. What limits the practical exploitation of the multidimensional multiplex advantage is the current unavailability of a suitable algorithm to derive the higher order Wiener kernels from finite-length excitation and response records free of systematic noise.

3.1 Quantum Mechanical Interpretation

The nonlinear cross-correlation functions and, by equation (3), the Wiener kernels, have been calculated in Liouville space.^{24,25} It turns out that they can be interpreted in terms of a multipulse response reminiscent of multidimensional FT NMR. This is illustrated in Figure 3 together with the Liouville space expression of c_3 . Time proceeds from right to left. Instead of a thermodynamic equilibrium density matrix $\hat{\rho}_\infty$ the density matrix $\hat{\rho}'_\infty$ in equilibrium with the uninterrupted stochastic excitation appears. $\hat{B}$ is a superoperator that is the first-order term of the pulse rotation operator. Thus, it is referred to as the pseudopulse operator. It changes the

Figure 3 Liouville-space expression for the third-order correlation function (top) and graphical interpretation (middle) in terms of a 3D experiment with pseudopulse excitation. Each pseudopulse $\hat{B}$ induces transitions by $|\Delta m| = 1$ in the density matrix, giving rise to the coherence transfer diagram depicted at the bottom. Note that time proceeds from right to left

coherences in a given response order of the density matrix by exactly $\Delta m = \pm 1$. $\hat{F}_-$ is the operator describing quadrature detection, and $\exp(\hat{C}t)$ is the Liouville operator for the nuclear spin precession around the z axis with saturation effects included, which derive from the continuous presence of the excitation. For weak excitation, $\exp(\hat{C}t)$ approaches the operator of the free induction decay. The remaining difference from multidimensional pulse NMR is the nomenclature for the time variables. In stochastic NMR, the natural quantities are the time displacements σ_i or τ_i from the present t to the event (pseudopulse) in the past, while in pulse NMR, the pulse separations t_i are used.^{37,38}

The interpretation of the correlation function in terms of successive pairs of pseudopulse operators $\hat{B}$ and evolution operators $\exp(\hat{C}t)$ leads to an intuitive understanding of correlation functions in stochastic NMR.³⁶ For example, for fixed t_1 and very short t_2 , the stochastic equivalent of the $90^\circ - t_1 - 180^\circ - t_3$ excitation is obtained, and an echo is observed for $t_3 = t_1$ in the respective 1D cross-section through the third-order correlation function (Figure 4).^{31,39}

From the pseudopulse interpretation of correlation functions, it is clear that the time shifts σ_i and τ_i are time-ordered by causality (see Figure 3). Nevertheless, the Wiener approach is based on symmetric kernels $h_{ns}(\sigma_1, \dots, \sigma_n)$. Here, the time order has been lifted by sweeping the delays in the cross-correlation function, equation (3), through equal ranges, independent of each other, though the complete information is already obtained in the section of 3D time-displacement space,³⁸ where, for instance,

$$\sigma_1 \geq \sigma_2 \geq \sigma_3 \quad (4)$$

by which the Fourier transforms of the kernels $h_{ns}(\sigma_1, \dots, \sigma_n)$ can be evaluated. This is convenient in practice, because the fast Fourier transformation algorithm can be used, and higher order stochastic NMR spectra can be evaluated at the frequency regions of interest only. For practical purposes, this is particularly important for evaluation of the third order response in terms of a 3D spectrum $H_{3s}(\omega_1, \omega_2, \omega_3)$. Denoting time domain expressions by lower case letters and frequency domain expressions by capital letters, one obtains

$$H_1(\omega) = \frac{\langle Y(\omega) X^*(\omega) \rangle}{\langle |X(\omega)|^2 \rangle} \quad (5)$$

$$H_{3s}(\omega_1, \omega_2, \omega_3) = \frac{\langle Y_3(\omega_1 + \omega_2 + \omega_3) X^*(\omega_1) X^*(\omega_2) X^*(\omega_3) \rangle}{3! \langle |X(\omega_1)|^2 \rangle \langle |X(\omega_2)|^2 \rangle \langle |X(\omega_3)|^2 \rangle} \quad (6)$$

where

$$Y_3(\omega) = H_1(\omega) X(\omega) \quad (7)$$

With reference to equation (3), the second moment μ_2 of the excitation has been replaced by the mean power spectral density $\langle |X(\omega)|^2 \rangle$. The angle brackets denote ensemble averages over excitation and response sample spectra, respectively, to reduce the variance of the stochastic response, which manifests itself in terms of systematic noise in stochastic NMR spectra. In fact, this systematic noise is a severe limitation on practical use of the technique. Therefore, considerable effort has been spent in devising schemes alternative to equations (5)–(7) that extract the Fourier transforms of the Wiener kernels at better ratios of signal to systematic noise.

3.2 Frequency Domain

Fourier transformation of the cross-correlation expression in equation (3) and use of the Wiener series expansion in equation (2) for the system response $y(t)$ leads to expressions

3.3 Experimental Examples

The Wiener theory is applicable to the analysis of nonlinear systems with zero-mean Gaussian white noise excitation. The optimum excitation power is determined by the maximum

Figure 4 (a) Timing diagram for the cross correlation delays σ_i to observe an echo. (b) Stochastic echo of water doped with copper(II) sulfate in an inhomogeneous magnetic field for $t_1 = \sigma_1 - \sigma_2 = 720 \mu\text{s}$. (c) Stochastic echo for $t_1 = 960 \mu\text{s}$

amplitude of the stochastic transverse magnetization response [see Figure 2(a)].¹⁹ In practice, often noise with non-Gaussian probability distributions is used. For such excitation, the Wiener description of the nonlinear response can be extended.¹⁹

3.3.1 Liquids

Stochastic excitation is most easily applied in liquid state NMR, where transverse and longitudinal relaxation times are about equal. Here, the maximum signal response is obtained. If T_1 is much longer than T_2 , the excitation power needs to be reduced to avoid complete saturation, and the response amplitude decreases accordingly. In practice, 1D and 2D stochastic NMR spectra have been calculated from equations (5) and (6), respectively, where a COSY-like 2D spectrum is obtained from equation (6) by setting $\omega_3 = -\omega_2$ (Figure 5b). Three-dimensional peaks outside of this 2D cross-section elsewhere in the 3D spectrum provide connectivities of three single quantum transitions.³⁸ High spectral resolution can be obtained in all dimensions of multidimensional stochastic NMR spectra, because the resolution is determined for all

dimensions by the length of the sample records, which are averaged after Fourier transformation.

Figure 5 illustrates such stochastic NMR spectra with the Fourier transform $H_1(\omega)$ of the first-order Wiener kernel and the 2D cross-section $H_{3s}(\omega_1, \omega_2, -\omega_2)$ of a mixture of ethanol and acetylacetone in methanol- d_4 .⁴⁰ The 2D cross-section has been evaluated only at the frequency coordinates of interest, which have been identified in the 1D spectrum. The signals in the 2D spectrum are each a sum of four contributions, because the spectrum is a cross-section through the Fourier transform of a symmetric Wiener kernel.⁴¹ The individual contributions exhibit different lineshapes and different physical origins. They arise from connectivities of the single quantum coherences, which are plotted along the spectral axes via common energy levels (population effects), and zero and double quantum transitions. These connectivity types correspond to the coherence orders present during the evolution time t_2 in the coherence transfer diagram of Figure 3. Because there is a population path associated with an evolution time, these cross-sections are sensitive to chemical exchange and cross relaxation. However, because they are essentially derived from a 3D Fourier transform, the exchange signals are associated with the integral over all mixing times up to the length of the sample record.

3.3.2 Solids

In solids, T_1 is usually larger than T_2 , and the amplitude of the response to stochastic excitation is weak. Nevertheless, spectrometers are sensitive enough for acquisition of the stochastic solid state response. Figure 6 depicts ^1H spectra of natural rubber for a nonspinning sample and under MAS.⁴² Clearly, there are no fundamental complications with stochastic excitation and MAS in solids. In fact, even MAS imaging experiments have already been performed with noise excitation.⁴²

For practical purposes, the use of noise excitation is of interest in wide-line NMR of powder and partially oriented samples. Here, pulsed excitation requires the use of an echo to overcome receiver deadtime. This leads to complications in the intermediate exchange regime, where the signal decays substantially within the deadtime. With low-power stochastic excitation, the deadtime can be shortened. The equivalence in terms of sensitivity of pulsed and Hadamard excitation is demonstrated in Figures 7(a) and (b), where equal signal-to-noise ratios are obtained for the ^2H resonance of hexamethylbenzene- d_{18} .⁴³ This, however, applies only for large filter bandwidths, because the time sharing principle requires multipulse conditions in the experiment. When the echo is detected instead [Figure 7(c)], a matched filter can be used, and the signal-to-noise ratio improves. Time sharing can be discarded and matched filters can be used if crossed receiver and transmitter coils are employed, or if the excitation is realized by random magnetic field modulation.¹⁰ In this case, even ^{14}N NMR of disordered solids may become feasible with stochastic excitation.

4 IMAGING

The most useful feature of stochastic excitation in NMR is the low power compared with pulsed excitation. The rf

Figure 5 (a) 1D stochastic NMR spectrum or Fourier transform of the first-order Wiener kernel of a mixture of ethanol and acetylacetone in methanol- d_4 . The spectrum was computed from 10^6 excitation and response data pairs using equation (5). (b) 3D frequency cube $H_{3s}(\omega_1, \omega_2, \omega_3)$ of the Fourier transform of the third-order Wiener kernel and location of the subdiagonal 2D cross section $H_{3s}(\omega_1, \omega_2, -\omega_2)$. (c) Subdiagonal 2D cross-section $H_{3s}(\omega_1, \omega_2, -\omega_2)$ of the frequency regions of interest in (a) computed from the same data as the 1D spectrum using equation (6)

Figure 6 Stochastic ^1H spectra of natural rubber from 16 K complex excitation and response data pairs each. The excitation was four-phase constant-amplitude noise. (a) Spectrum of the static sample. (b) MAS spectrum

power is proportional to the square of the magnetic field amplitude. While the particular optimum excitation amplitude depends on the nuclear relaxation times, typical average flip angles in a string of stochastic rf pulses are of the order of 0.1° – 10° . Thus, the rf amplitude is reduced by a factor of about 10^2 compared with pulsed NMR, so that a factor

of 10^4 can be saved for the excitation power. This is of interest not only in wideline spectroscopy, but also for whole body investigations of large objects and for imaging at high magnetic fields. For this reason, stochastic excitation has been explored for medical^{28–30,44} as well as materials imaging.^{42,44} Two approaches are distinguished. One is based on cross correlation and time-dependent magnetic field gradients; the other is based on the back-projection technique.

4.1 Cross Correlation

In the presence of time-dependent magnetic field gradients, the nuclear spin response can be described in terms of the linear system response $y_1(t)$ to four inputs.²⁸ These are the rf excitation and the gradient modulations in the three space directions. If $M_0(\mathbf{r}, \omega)$ is the spin density, which depends on the space coordinate vector $\mathbf{r}$ and the chemical shift ω , then the linear response kernel $k_1(t)$ can be written for liquid systems as the integral over all FID signals for each space coordinate $\mathbf{r}$ and each chemical shift ω :

$$k_1(t) = \int \int M_0(\mathbf{r}, \omega) \exp \left[- \left(\frac{1}{T_2} - i\omega \right) t \right] d\omega \times \exp[i\mathbf{k}(t, 0) \cdot \mathbf{r}] d^3r \quad (8)$$

Here $\mathbf{k}(t, 0)$ is the Fourier conjugate of the space vector $\mathbf{r}$, proportional to the time integral of the gradient vector $\mathbf{G}$ from

Figure 7 Comparison of solid echo and Hadamard spectra of the ^2H resonance of hexamethylbenzene- d_{18} . All spectra were acquired in 5 s. (a) Solid echo spectrum, 500 kHz filter bandwidth. (b) Hadamard spectrum, 500 kHz filter bandwidth. (c) Solid echo spectrum, matched filter with 30 kHz bandwidth. The power of the stochastic rf excitation was 100 mW

time zero to t . First-order cross correlation of the system response, equation (2), with the linear kernel, equation (8), according to

$$c_1(\mathbf{r}, \sigma) = \int y(t) \exp[-i\mathbf{k}(t, t - \sigma) \cdot \mathbf{r}] x^*(t - \sigma) dt \quad (9)$$

can produce the spin density as a function of $\mathbf{r}$ weighted with the FID as a function of σ for each position $\mathbf{r}$.²⁸ Thus, in the cross correlation in equation (9) both $\mathbf{r}$ and σ need to be varied. Spectroscopic images of phantoms have been obtained in this way.²⁹ The cross-correlation approach can, in principle, be extended to incorporate the nonlinear response for stochastic imaging with 2D spectroscopic resolution.¹⁸ Random, oscillating, and rotating gradients have been investigated in the context of the cross-correlation approach.

4.2 Back-Projection

Experimentally, the least demanding gradients are static only. In this case, projections of the object are derived from the linear response to stochastic excitation. Both random noise⁴⁴ and Hadamard excitation^{30,45} have been explored. The Hadamard technique promises to be of most interest, because the projections can be obtained free of systematic noise, so that extensive averaging is unnecessary. Thus, the method is fast. Imaging times have been estimated as 3 min for 3D images with 256^3 voxels and as 2 s for 2D images with 256^2 pixels. However, in either case, slice selection poses a problem, because the conventional theory applies to dynamic equilibrium of the response with the noise excitation. Slice selection would invariably violate this equilibrium and lead to turn-on effects, which result in noise-like signal degradations.^{14,43} But, in some cases, these turn-on effects can be neglected, and a theory can be devised that inverts the linear convolution in equation (2), taking care of the

Figure 8 Surface-rendered 3D image of an olive reconstructed from 12 projections. Hadamard excitation has been used in combination with low-power slice selection. Mean excitation flip angle 1.1° ; slice dimension 127×127 pixels calculated from 64 projections; slice thickness 1.6 mm; field-of-view $4 \text{ cm} \times 4 \text{ cm}$ per slice. Signals are observed from the meat of the olive as well as from the interior of the pit

fact that the noise excitation has been turned on at time $t = 0$. Figure 8 demonstrates the use of the Hadamard technique in combination with the back-projection method and slice selection by a surface-rendered 3D image of an olive reconstructed from 12 projections. To preserve the low-power advantage of stochastic excitation during slice selection, low-power presaturation needs to be employed.⁴⁶

5 INTERFERENCE

The multidimensional cross correlation in equation (3) can be evaluated numerically from experimental excitation and response records or in an analog fashion during the experiment. In the latter case, only the cross-correlation function is recorded as a function of the time shifts σ_i . A one-dimensional correlator based on this principle is the Michelson interferometer.^{47,48} In Figure 9, the block diagram of a first-order cross correlator with a single delay σ is compared with a modified Michelson interferometer. The white noise source is white light, the time shift is introduced by variation of the optical path length, and the formation of the product of excitation and response signals as well as the integration over time are achieved in a slow intensity detector, which detects the squared magnitude of the time-averaged sum of electromagnetic fields impinging on its surface. Such an

Figure 9 (a) First-order cross correlator. The time delay σ is varied to scan the cross-correlation function $h_1(\sigma)$ of excitation $x(t)$ and response $y(t)$. (b) A Michelson interferometer modified for measurement of the cross-correlation function. The time delay σ is introduced by a pathlength variation via a movable mirror

analog device is particularly suitable for measurement of cross-correlation functions of signals, which are too fast for direct sampling. The interferogram can be sampled as slowly as the delay σ is varied.

The Michelson interferometer is the heart of a Fourier infrared spectrometer. Here, the correlation function is called an interferogram. Thus, linear stochastic NMR is equivalent to Fourier spectroscopy in the optical regime.⁴⁷ Moreover, there is an equivalence between correlation and interference. Given the fact that nonlinear cross-correlation functions are defined and can be evaluated in stochastic NMR, nonlinear interference can be defined in optics as the analog realization of higher order cross correlation [cf. equation (3)].^{49,50} In fact, to demonstrate this equivalence experimentally, the NMR echoes of Figure 5(b) have been recorded by scanning the time delay σ_3 in a third-order cross correlator built from electronic components.³⁹ Thus, the stochastic echo is an example of a nonlinear interferogram. The closeness of the Wiener series perturbation approach to nonlinear optics is further underlined by the fact that the Volterra kernels are the Fourier transforms of the nonlinear susceptibilities in optics, and that the Wiener kernels are equivalent to the Volterra kernels apart from excitation-power-dependent saturation effects.

The echo is the fundamental phenomenon that introduces two time axes into spectroscopy: one, the echo time, measures the position of the echo maximum, and the other the rise and

decay of the echo itself. Thus, 2D spectra can be derived from a set of echoes that have been measured in a systematic fashion for several echo times. To overcome the low signal-to-noise ratio of the third-order cross-correlation function and the necessity of multiplying four broadband optical signals, an alternative route to stochastic echoes can be followed. Instead of a single noise source $x(t)$, a time-shifted sum excitation is used:³²

$$x'(t) = x(t) + rx(t - \sigma_1) \quad (10)$$

where r is a scaling factor. The nonlinear response of the system to this excitation is evaluated. This has been done in optics by recording the intensity of the third-order response as a function of the time shift σ_1 . The resultant autocorrelation function has been termed an incoherent echo. It has been shown to reveal information about T_1 and T_2 .⁵¹⁻⁵³ However, a true echo is characterized by two time parameters. These can be introduced by evaluating the first-order cross-correlation function of the nonlinear response to the sum excitation with $x(t - \sigma_2)$. An optical device that does this in an analog fashion can readily be built by combining the Michelson interferometer with the incoherent echo experiment [Figures 10(a) and (b)].³² By phase cycling the components of the sum excitation, 2D spectra reminiscent of COSY NMR spectra can be derived in the optical regime, which can help to unravel the energy level structure of molecules from high-resolution data obtained in the gas phase or by matrix isolation techniques. The result of a simulation in the case of NMR for a high-resolution AB system is depicted in Figure 10(c). A COSY spectrum is obtained at a remarkably good signal-to-noise ratio. The good signal-to-noise ratio results from the fact that the response probes all odd orders of Wiener functionals because the sum excitation is no longer white.

6 QUO VADIS?

Stochastic excitation in NMR started out from pure curiosity. Noise decoupling for a long time has been the superior decoupling method in liquid state NMR. The acquisition of NMR spectra with noise excitation has never become popular, because of the superior features of pulsed FT NMR for dedicated rf manipulation of nuclear spin interactions and for the possibility of designing special experiments tailored to the information required. With stochastic NMR based on the Wiener series, all the available information is acquired in a single experiment, and it is sorted out during data processing. Here, however, the problem of systematic noise enters, which prohibits a clean separation of information as a result of the statistical nature of the excitation in connection with finite-length excitation and response records. Consequently, schemes that produce spectra with better signal-to-noise ratios by sacrificing the generality of the excitation but retaining the excitation power advantage appear most promising for practical use.

Examples of such schemes are Hadamard excitation for the linear response and the time-shifted sum excitation for interrogation of the nonlinear response. The low power of the stochastic excitation reduces probe ringing, relaxes the requirements for high-power amplifiers in spectroscopy and imaging, reduces the power heating in dissipative objects, and gives access to larger spectral width. Areas where these

(b) Schematic diagram showing the principle experimental set-up. The experiment combines the Michelson interferometer with the incoherent echo experiment. The spatial separation of optical signals from different response orders is not shown. (c) Fourier transform of a 2D interferogram simulated for an AB system in high-resolution NMR, including phase cycling of the excitation sum for elimination of unwanted terms

features of interest are in medical and materials imaging, and in wide-line spectroscopy, such as in solid state ^2H and ^{14}N NMR, in EPR, and in NQR spectroscopy.

The time-shifted sum excitation is particularly intriguing for several reasons.

1. The excitation power is as low as for true white-noise excitation, yet the excitation spectrum carries a sinusoidal modulation.
2. The data processing can readily be achieved in the optical regime with analog components.
3. The signal-to-noise ratio of the linear correlation function of the nonlinear response is high, because a superposition of Wiener kernel transforms from all response orders is observed.
4. Phase cycling can be used in the sum excitation for elimination of artifacts and unwanted response contributions. A most fascinating outlook is the use of such excitation for the

generation of optical 2D spectra. In fact, Hadamard excitation has already been used to acquire ultrahighly resolved optical 1D spectra.⁵⁴

The bottom line of stochastic excitation 50 years after the discovery of NMR is that its investigation has produced a thorough understanding of nonlinear incoherent spectroscopy. This is the counterpart of nonlinear coherent spectroscopy, which traditionally belongs to the optical regime, where coherent laser irradiation is standard, but the development of incoherent excitation sources of sufficient strength for excitation of the nonlinear response has been neglected.

1 INTRODUCTION

Much modern solid-state NMR technology is based on two physical manipulations: (i) rotation of the sample in space, usually at a fixed frequency around a fixed axis, but sometimes using more complicated trajectories; and (ii) rotation of the nuclear spin polarizations using applied rf fields.

Magic-angle spinning was first demonstrated independently by Andrew and Lowe^{1,2} in 1959. These researchers demonstrated a noticeable narrowing effect on the NMR spectra of abundant spins in solids when the sample was rotated at several kHz around an axis tilted by the angle $\arctan \sqrt{2} = 54.74^\circ$ with respect to the main magnetic field (see **Magic Angle Spinning**, Volume 5). However, the magic-angle spinning (MAS) method was not employed much at first because it was thought to be ineffective unless the spinning frequency greatly exceeded the size of the anisotropic nuclear spin interactions – a condition difficult to satisfy except for a limited number of samples. The situation changed at the end of the 1970s, when it was found that magic-angle spinning dramatically narrowed the proton-decoupled NMR peaks of isolated ^{13}C spins in organic solids.³ The ^{13}C peaks split up into narrow ‘spinning sidebands’, even though the spinning frequency was much smaller than the chemical shift anisotropy (CSA). MAS, in combination with Hartmann–Hahn cross-polarization and heteronuclear decoupling, became a standard method for examining the NMR spectra of rare spin species such as ^{13}C and ^{15}N in solids.⁴ Commercial NMR companies began to offer MAS equipment as options for their spectrometers, allowing an explosion of applications.

The use of nuclear spin rotations by applied rf fields developed in parallel. The basic technique of heteronuclear decoupling was already introduced by Bloch,⁵ and advanced rapidly in the context of solution NMR with the introduction of noise modulation⁶ and composite pulse decoupling^{7–9} (see **Decoupling Methods**, Volume 3). In solid-state NMR, on

the other hand, heteronuclear decoupling methodology stagnated until the introduction of the two-pulse phase modulation (TPPM) by Griffin and co-workers.¹⁰ The methodology of homonuclear dipolar decoupling in solids received more attention from the start. This process started with the use of magic-angle off-resonance irradiation by Lee and Golburg¹¹ and continued with the pulse methods of Waugh, Huber and Haeberlen,^{12,13} Mansfield,¹⁴ Rhim and Vaughan,¹⁵ Burum and co-workers¹⁶ and many others (see **Average Hamiltonian Theory**, Volume 2). Advances in digital electronics made possible new approaches, such as the frequency-switched Lee–Goldburg (FSLG) method.¹⁷ These methodological developments were accompanied by important theoretical advances such as the average Hamiltonian theory and its variants.^{13,14,18}

For much of this period, the spatial and spin manipulations were treated separately. For example, the principles of homonuclear decoupling by applied rf fields were developed explicitly for static samples – the rotation of the sample during the rf pulse sequence, in the case of MAS, was regarded as a minor additional perturbation. Similarly, the principles of echo formation by sample rotation generally neglected the duration of applied rf pulses. This conceptual separation was made possible by an experimental separation of timescales. Routinely-available spinning frequencies were much smaller than routinely-available nutation frequencies under applied rf fields. This situation was not fundamentally changed even when the ‘combined rotation and multiple pulse sequence’ (CRAMPS) methods were introduced^{19,20} (see **CRAMPS**, Volume 3). At the rather low spinning frequencies used initially, it was a reasonable approximation to ignore the MAS rotation during the rf pulse sequence. The enhanced narrowing effect of CRAMPS could be treated roughly by tacking the MAS rotation onto the end of a static average Hamiltonian calculation.

At the beginning of the 1980s, two developments highlighted the fact that rf pulse sequences and sample rotation could combine in unexpected and powerful ways. In the extraordinary sideband suppression and separation schemes of Dixon,^{21,22} carefully-timed sequences of strong π pulses were applied to the rotating sample in order to manipulate the spinning sideband patterns generated by the subsequent free-induction decay. Around the same time, Waugh and co-workers applied a repetitive pulse train synchronous with the sample rotation, and showed that the averaging effect of the magic-angle rotation on the chemical shift anisotropy could be suppressed.²³ This would now be called a ‘CSA recoupling’ experiment.

The term ‘recoupling’ was first used in the heteronuclear context, when it was shown that the application of a continuous rf field to one spin species may restore the effect of the heteronuclear dipolar interaction to a second spin species, by counteracting the averaging effect of the magic-angle rotation.^{24,25} This requires selection of the rf amplitude so that the magic-angle rotation frequency is a small integer multiple of the nutation frequency under the rf field, a condition termed ‘rotary resonance’. It was also pointed out that the same effect could be produced by applying two strong 180° pulses every rotational cycle to one of the spin species.²⁵ This idea was developed independently by Schaefer et al., leading to the highly-successful rotational echo double resonance (REDOR) method^{26,27} (see **REDOR & TEDOR**,

Volume 6). As discussed below, the REDOR scheme fits into the symmetry theory of rotor-synchronized pulse sequences (in the modern notation defined below, the symmetry of the usual version of REDOR is $R4_1^1$).

The next important advances were made by Tycko and co-workers.^{28,29} It was shown that rotor-synchronized pulse sequences, in combination with sample rotation about a non-magic-angle axis, could be used to emulate a zero-field NMR experiment (see **Zero Field NMR**, Volume 8). In the context of the present article, it is important to note that Tycko used symmetry relationships to simplify the task of pulse sequence design. In the modern notation defined below, one would describe Tycko's 'zero-field in high-field' pulse schemes as having the symmetry $C5_1^1$.

The second development made by Tycko's group also had a wide impact. The dipolar recoupling at the magic angle (DRAMA) scheme^{30–32} initiated the field of *homonuclear* dipolar recoupling in solids (see **Homonuclear Recoupling Schemes in MAS NMR**, Volume 4). DRAMA is a rather simple pulse sequence of strong 90° pulses separated by intervals and is not particularly robust. A partially successful attempt was made to improve it using symmetry-based arguments.³² A popular alternative is the radio-frequency driven recoupling (RFDR) scheme of Griffin and co-workers, which is based on strong 180° pulses.^{33,34} As discussed below, part of the success of RFDR may now be understood in terms of its symmetry properties (in modern notation, the symmetry of the usual version of RFDR is $R4_1^1$).

A different approach to dipolar recoupling was introduced with the double-quantum homonuclear rotary resonance (2Q-HORROR) method.³⁵ This was a development of the heteronuclear rotary resonance method, exploiting the additional resonance conditions associated with double-quantum transitions in homonuclear spin systems. The HORROR method showed for the first time that it is possible to achieve highly efficient 2Q excitation in a powder sample, in part by a tighter control of the orientation-dependence of the recoupled Hamiltonian. The appropriate property has come to be called " γ -encoding", and will be discussed below.

HORROR is only feasible for coupled spins with small chemical shift differences. It required a fresh theoretical approach to extend this method to more general systems while retaining the γ -encoded 2Q recoupling property. This effort led to the C7 pulse scheme and its variants,^{36–42} which are capable of efficient broadband double-quantum recoupling. In modern notation, these schemes have the symmetry $C7_1^1$. These methods were applied to a variety of problems, including the measurement of molecular torsional angles in a membrane protein.^{43,44}

As well as being practically successful, the theory behind C7 was very powerful, and could be used for a variety of problems. A further extension of the symmetry theory led to a palette of symmetries suitable for γ -encoded double-quantum recoupling, including methods which are applicable at high spinning frequencies.³⁹ The symmetry theorems were also used to treat the problem of heteronuclear decoupling in MAS solids, generating schemes competitive with the TPPM modulation method.^{41,45}

In a related development, Spiess and co-workers showed that CRAMPS may be implemented at high MAS spinning frequencies by synchronizing the rf cycles with the sample

rotation.^{46,47} In modern notation, these schemes have the symmetry $C3_1^0$ and $C4_1^0$.

Schemes such as C7 are based on repeated radio-frequency cycles, shifted in phase and synchronized with the sample rotation. Each cycle is designed to return the nuclear spins to their initial states, if other spin interactions are ignored, i.e., each cycle provides a rotation through 0° , 360° , or 720° , etc. Although effective for double-quantum excitation, this construction scheme is too restrictive when applied to many other recoupling problems. A set of new symmetries were therefore developed, based on 180° rotation elements.⁴¹ These symmetries, called *R*-symmetries, suggest many new classes of pulse sequence, and also help explain the operation of many existing schemes. As discussed below, many of the successful methods invented in the past, such as RFDR, REDOR, and TPPM conform to the *R*-symmetries. This is probably not a coincidence.

The invention of *R*-symmetries was anticipated by the through bond spectroscopy (TOBSY) method of Baldus and Meier.^{48–52} These authors also used symmetry arguments to design their pulse sequences, which have the modern symmetry notation $R6_1^0$ and $R8_1^0$.

The discovery of the *R*-symmetries is still too recent to assess their full significance. Some of the promising recent applications are discussed below.

2 HOMONUCLEAR SEQUENCES

2.1 Spin Interactions

The symmetry-based approach to the design of rotor-synchronized pulse sequences exploits the rotational properties of the nuclear spin interactions. In general, each spin interaction may be expressed as a product of three terms, expressing the transformation properties of the interaction with respect to rotations of the molecular framework ('space'), rotations of the nuclear spin polarizations ('spin') and rotations of the external magnetic field. These rotational properties may be summarized in terms of the three *rotational ranks* which define each nuclear spin interaction. The set of rotational ranks forms the *rotational signature* of a nuclear spin interaction. The rotational signatures are summarized for the most important homonuclear interactions of spin-1/2 in Table 1.

As may be seen from Table 1, the significant nuclear spin interactions all have ranks 0, 1 or 2. For example, those interactions which are invariant to a particular type of rotation are assigned rank zero. Interactions which have the rotational symmetry of a p-orbital in atomic theory are assigned rank 1. Interactions which have the rotational symmetry of a d-orbital in atomic theory are assigned rank 2.

Consider, for example, the homonuclear dipolar interaction between nuclear spins. This has rank 2 with respect to both

Table 1 Rotational signatures of homonuclear spin interactions in diamagnetic systems of spin-1/2

Interaction	Space rank, l	Spin rank, λ	Field rank
Isotropic chemical shift	0	1	1
Chemical shift anisotropy	2	1	1
J -coupling	0	0	0
Dipole–dipole coupling	2	2	0

spatial and spin rotations, indicating, for example, that a rotation of the molecular framework by 180° does not change the interaction strength, while a rotation through 90° changes the sign of the interaction.

The chemical shift anisotropy interaction is more complicated, since it is a three-body interaction, involving the nuclear spins, the electronic environment and the external magnetic field. It has ranks 2, 1 and 1 with respect to molecular rotations, spin rotations, and external field rotations, respectively. This interaction changes sign if the nuclear spins are rotated by 180° , with the molecules and the field held fixed. The CSA interaction also changes sign if the external field is rotated through 180° , while the spin polarizations and the molecular environment are held fixed. The CSA interaction does not change sign, on the other hand, if the molecules are rotated through 180° , while the spins and the field are held fixed.

Many NMR textbooks conflate the ‘spin’ part and the ‘field’ part into one compound term, often called, confusingly, the ‘spin part’ of the interaction. This practice obscures the rotational properties and is best avoided.

There are also minor interactions such as the antisymmetric part of the chemical shift tensor (space, spin, field ranks of 1, 1 and 1), and the J -coupling anisotropy (space, spin, field ranks of 2, 2 and 0), which are omitted here for simplicity.

The spherical ranks listed in Table 1 are defined as follows: An irreducible spherical tensor of rank l has $2l + 1$ components, with a component index m running from $-l$ to $+l$ in integer steps. A rotation interconverts these $2l + 1$ components according to the transformation equation:

$$R(\Omega)T_{\lambda m}R(\Omega)^\dagger = \sum_{m'=-l}^{+l} T_{\lambda m'}D_{m'm}^l(\Omega) \quad (1)$$

Here $R(\Omega)$ are rotation operators and $D_{m'm}^l(\Omega)$ is an element of the $(2l + 1)$ -dimensional Wigner matrix. The symbol Ω indicates a triplet of Euler angles $\Omega = \{\alpha, \beta, \gamma\}$ defining a general three-dimensional rotation. Irreducible spherical tensors, Wigner matrices and Euler angles are discussed thoroughly in the literature.⁴ A particularly useful compilation is given in Ref.⁵³ The article **Internal Spin Interactions & Rotations in Solids**, Volume 4, summarizes many key results.

The Wigner elements have the following form:

$$D_{m'm}^l(\Omega) = \exp\{-im'\alpha\}d_{m'm}^l(\beta)\exp\{-im\gamma\} \quad (2)$$

where $d_{m'm}^l(\beta)$ is called a reduced Wigner matrix element.

Although the detailed form of the Wigner matrices and the spherical tensors depends on the rank, and the approach appears to be mathematically complicated at first sight, the transformation properties are always the same, which permits a universal approach to pulse sequence theory.

2.2 Reference Frames

The discussion of spin interactions in rotating solids is facilitated by defining a set of reference frames (Figure 1).

2.2.1 The Principal Axis Frame P^Λ

The *principal axis frame* P^Λ provides the simplest form of the spin interaction Λ . For example, consider the through-space dipole–dipole interaction (DD interaction) between two

Figure 1 Definition of the reference frames in magic-angle spinning NMR experiments. (Adapted from Ref.⁸²)

spins j and k . The z -axis of the principal axis frame P^{jk} is oriented along the vector joining the spins j and k . In this frame, the spherical tensor components with $m = \pm 1$ and $m = \pm 2$ vanish, leaving only the $m = 0$ component. For the CSA interaction of spin j , the $m = \pm 1$ components vanish in the principal axis frame P^j , while the $m = 0$ and $m = \pm 2$ components remain finite.

In general, there are many different spin interactions, and each one has a different principal axis frame P^Λ .

2.2.2 The Molecular Frame M

The molecular reference frame M is fixed with respect to the molecular structure. It is usual to transform all of the different spin interactions into the common reference frame M before further manipulations are imposed.

A principal axis frame P^Λ is related to the molecular frame M by a set of three Euler angles, denoted $\Omega_{PM}^\Lambda = \{\alpha_{PM}^\Lambda, \beta_{PM}^\Lambda, \gamma_{PM}^\Lambda\}$. These Euler angles define the relative orientation of the frames P^Λ and M . In general, there are several spin interactions, each with a different set of Euler angles Ω_{PM}^Λ , specifying its orientation with respect to the common molecular frame M .

2.2.3 The Rotor Frame R

In a spinning solid, the orientation of the molecules with respect to the rotating sample holder (‘rotor’) is of great importance. The rotor-fixed frame R is defined such that its z -axis is along the rotational axis. The Euler angles $\Omega_{MR} = \{\alpha_{MR}, \beta_{MR}, \gamma_{MR}\}$ define the relative orientation of the molecular reference frame and the rotor frame.

If the sample were a single crystal, with only one molecule in the asymmetric unit of the crystal structure, then all molecules in the sample would have the same set of Euler angles Ω_{MR} . In practice, the sample usually has an orientational distribution of some kind, and in the extreme case of a disordered sample such as a powder, the Euler angles Ω_{MR} are distributed randomly. In such cases, the results of experiments must be analyzed by integrating spin dynamical calculations

over all possible values of the Euler angles Ω_{MR} . This is called powder averaging.

The Euler angle γ_{MR} has special significance in the theory of rotating solids. Molecules which have the same values of α_{MR} and β_{MR} but different values of γ_{MR} are related by a rotation around the rotor axis. This implies that the mechanical rotation of the sample causes such molecules to pass through the same cycle of laboratory frame orientations, but with a mutual time shift. This concept has been called a *carousel*,⁵⁴ since the riders on a playground carousel follow the same circular path, but are shifted with respect to each other in time.

In some samples, it is convenient to include one or more reference frames intermediate between M and R . For example, in crystalline solids, it is common to define a crystal-fixed reference frame C , and a set of Euler angles $\Omega_{MC} = \{\alpha_{MC}, \beta_{MC}, \gamma_{MC}\}$ defining the orientations of the molecules with respect to the crystal axes. If there is more than one molecule in the crystal unit cell, then several sets of Euler angles Ω_{MC} are needed. The orientation of the crystal with respect to the rotor is defined through the Euler angles Ω_{CR} . In ordered samples such as fibres, on the other hand, it is useful to define a fibre director axis system D . The Euler angles Ω_{MD} relate the molecular axis system M to the fibre director system D , and a further set of Euler angles Ω_{DR} relate the fibre director to the rotor axis. By factorizing the problem in this way, it is possible to define independent orientation distributions for the molecules with respect to the fibre, and for the fibres with respect to the rotor. An example of this approach is found in Refs.^{55,56} If the sample is a powder, these intermediate axis systems are unnecessary, and they will be omitted in the following discussion.

2.2.4 The Laboratory Frame L

The laboratory frame is chosen so that its z -axis is along the external magnetic field. The relative orientation of the sample holder and the field are defined by the Euler angles $\Omega_{RL} = \{\alpha_{RL}, \beta_{RL}, \gamma_{RL}\}$.

In magic-angle spinning NMR, the sample rotates at a fixed angular frequency ω_r about a fixed axis, subtending the magic angle $\theta_{\text{magic}} = \arctan \sqrt{2}$ with respect to the magnetic field. In these circumstances, the relevant Euler angles are given by

$$\begin{aligned}\alpha_{RL} &= \alpha_{RL}^0 - \omega_r t \\ \beta_{RL} &= \theta_{\text{magic}} = \arctan \sqrt{2} \\ \gamma_{RL} &= \text{arbitrary}\end{aligned}\quad (3)$$

Here α_{RL}^0 defines the orientation of the rotor at time point $t = 0$, which is rigorously defined as the start of signal acquisition (to be consistent with the normal definition of the Fourier transform, which involves an integral from $t = 0$ to $t = \infty$). If the rotation of the sample is not synchronized with the pulse sequence, the angle α_{RL}^0 varies randomly from transient to transient. If necessary, the rotation of the sample may be synchronized optically with the pulse sequence, so as to obtain reproducible and controllable values of α_{RL}^0 . This is usually unnecessary in powder samples.

The negative sign in the expression for α_{RL} is consistent with the usual definition of the Euler angles⁵³ and leads to

a right-handed rotation of the sample in the case that ω_r is positive.

The second Euler angle β_{RL} is the angle between the rotor axis and the field. For exact magic-angle spinning it is exactly equal to θ_{magic} , but for other experiments, such as off-axis spinning, variable-axis spinning, or “zero-field in high-field” experiments, the angle β_{RL} may take other values. In the rest of this article, exact MAS is assumed.

In double rotation or dynamical angle spinning experiments,^{57–59} the time-dependence of the Euler angles Ω_{RL} is more complicated (see **Double Rotation**, Volume 3). I ignore such possibilities here (double rotation may be handled neatly by introducing an ‘outer rotor’ frame as an intermediate between R and L).

2.3 Frame Transformations

The following ‘chain rule’ for the Wigner matrices greatly facilitates the transformations of spin interactions between the different frames:

$$D^I(\Omega_{AB})D^I(\Omega_{BC}) = D^I(\Omega_{AC}) \quad (4)$$

For example, a given spin interaction Λ may be transformed from its principal axis frame into the laboratory frame using equation (1) and the following chain:

$$D^I(\Omega_{PM}^{\Lambda})D^I(\Omega_{MR})D^I(\Omega_{RL}) = D^I(\Omega_{PL}^{\Lambda}) \quad (5)$$

Note the pattern of the subscripts. This notation greatly facilitates the task of concatenating multiple frame transformations.

2.4 Rf Euler Angles

The mathematics of spherical tensor rotations may also be applied to the rotations of the nuclear spin polarizations by resonant rf fields. In general, a sequence of resonant rf fields induces a time-dependent rotation of the resonant spins, which may be expressed as follows:

$$U_{\text{rf}}(t, t^0) = \exp\{-i\alpha_{\text{rf}}(t)I_z\} \exp\{-i\beta_{\text{rf}}(t)I_y\} \exp\{-i\gamma_{\text{rf}}(t)I_z\} \quad (6)$$

Here U_{rf} is the propagator under the applied rf fields, starting from the initial point of the pulse sequence, denoted t^0 , up to an arbitrary time t , and $\{I_x, I_y, I_z\}$ are the total angular momentum operators of the resonant spin species. In general, the propagator may be determined by integrating the Schrödinger equation:

$$\frac{d}{dt}U_{\text{rf}}(t, t^0) = -i\mathcal{H}_{\text{rf}}(t)U_{\text{rf}}(t, t^0) \quad (7)$$

under the boundary condition $U_{\text{rf}}(t^0, t^0) = \mathbf{1}$. The operator $\mathcal{H}_{\text{rf}}$ is the spin Hamiltonian for the interaction with the rf field, and depends on the amplitude, phase and frequency of the applied rf field in the usual way.

In general, the rf Euler angles $\Omega_{\text{rf}} = \{\alpha_{\text{rf}}, \beta_{\text{rf}}, \gamma_{\text{rf}}\}$ do not have an *obvious* relationship with the applied rf pulse sequence. Nevertheless, these angles provide a convenient way of defining the symmetry properties of the spins under rf irradiation, and it is always possible to derive the Euler angle

trajectory from a given pulse sequence. Furthermore, it also possible to discover the pulse sequence that provides a desired trajectory of rf Euler angles.

2.5 Rotational Components

The mechanical rotation of the sample induces a time-dependent trajectory of the Euler angles $\Omega_{RL} = \{\alpha_{RL}, \beta_{RL}, \gamma_{RL}\}$, while the rf pulse sequence induces a time-dependent trajectory of the Euler angles $\Omega_{rf} = \{\alpha_{rf}, \beta_{rf}, \gamma_{rf}\}$. Suppose that a certain spin interaction has space rank l and spin rank λ . According to equation (1), the spatial rotation induces a mixing of the $(2l + 1)$ space components with $m = -l, -l + 1 \dots + l$. Similarly, in the interaction frame of the rf field (see **Average Hamiltonian Theory**, Volume 2), the spin rotations induce a mixing of the $(2\lambda + 1)$ spin components with $\mu = -\lambda, -\lambda + 1 \dots + \lambda$.

In the presence of sample rotation and resonant rf fields, each spin interactions may therefore be regarded as a superposition of $(2l + 1) \times (2\lambda + 1)$ components, characterized by quantum numbers m and μ :

$$\mathcal{H}^\Lambda = \sum_{m=-l}^{+l} \sum_{\mu=-\lambda}^{+\lambda} \mathcal{H}_{lm\lambda\mu}^\Lambda \quad (8)$$

In the case of exact magic-angle spinning, the components with $l = 2$ and $m = 0$ vanish, due to the following property of the magic angle:

$$d_{00}^2(\theta_{\text{magic}}) = 0 \quad (9)$$

Explicit expressions for the components $\mathcal{H}_{lm\lambda\mu}^\Lambda$ may be found in Refs.^{45,60}

A summary of the spin interaction components, in the case of exact magic-angle spinning, is given in Table 2.

2.6 Symmetry Classes

The space and spin trajectories may be synchronized so as to generate an average Hamiltonian containing desired combinations of quantum numbers $\{l, m, \lambda, \mu\}$ while other combinations are suppressed.

This is done by setting up periodic symmetry relationships between the mechanical and rf rotations. Consider two arbitrary time points, separated by an interval $n\tau_r/N$, where n and N are integers, and $\tau_r = |2\pi/\omega_r|$ is the rotational period of the sample. From equation (3), the continuous rotation of the sample imposes the following relationship on the spatial Euler angles:

$$\begin{aligned} \alpha_{RL}\left(t + \frac{n\tau_r}{N}\right) &= \alpha_{RL}(t) - \frac{2\pi n}{N} \\ \beta_{RL}\left(t + \frac{n\tau_r}{N}\right) &= \beta_{RL}(t) \end{aligned} \quad (10)$$

The rf pulse sequence imposes similar-looking rules on the rf Euler angles (equation (6)).

In the case of CN_n^v sequences, the following Euler angle symmetry is imposed:

$$\begin{aligned} \beta_{rf}\left(t + \frac{n\tau_r}{N}\right) &= \beta_{rf}(t) \\ \gamma_{rf}\left(t + \frac{n\tau_r}{N}\right) &= \gamma_{rf}(t) - \frac{2\pi v}{N} \end{aligned} \quad (11)$$

where v is an integer, possibly different from n .

In the case of RN_n^v sequences, the Euler angle symmetry is slightly different:

$$\begin{aligned} \beta_{rf}\left(t + \frac{n\tau_r}{N}\right) &= \beta_{rf}(t) \pm \pi \\ \gamma_{rf}\left(t + \frac{n\tau_r}{N}\right) &= \gamma_{rf}(t) - \frac{2\pi v}{N} \end{aligned} \quad (12)$$

These symmetries apply to arbitrary time points within the pulse sequence.

The symbol CN_n^v and RN_n^v is called the *symmetry class* of the rotor-synchronized pulse sequence. The integers N , n and v are called the *symmetry numbers* of the pulse sequence. As will be seen, the symmetry class defines a set of *selection rules* for the average Hamiltonian, which may be used to manipulate the recoupling and decoupling properties of the pulse sequence.

2.7 Rotor-Synchronized Pulse Sequences

The symmetries in equations (11) and (12) only refer to two Euler angles; the behavior of the third Euler angle α_{rf} is left completely free. This freedom implies that there are many inequivalent ways of implementing equations (11) and (12). Some simple possibilities are described below.

2.7.1 CN_n^v Sequences

The CN_n^v Euler angle symmetries [equations (10) and (11)] are generated by rotor-synchronized pulse schemes of the general form shown in Figure 2. The idea is that n rotational periods of the sample are subdivided into N equal intervals. Each interval contains a radio frequency pulse sequence which is a *cycle*, i.e., it induces a rotation of the nuclear spins through an integer multiple of 360° (including zero). The radio-frequency phases of subsequent cycles are shifted with respect to each other by the angle $2\pi v/N$, causing a repeated incrementation (or decrementation) of the radio-frequency phase as one proceeds through the sequence. The integers n and v may therefore be interpreted as space and spin *winding numbers*.³⁹ The sample rotates bodily through n full rotations, in the same time that it takes the radio-frequency phases to

Table 2 Components of homonuclear spin interactions in the interaction frame of an applied rf field, in the case of exact magic-angle spinning

Interaction	Space rank, l	Space components, m	Spin rank, λ	Spin components, μ
Isotropic chemical shift	0	0	1	$\{-1, 0, 1\}$
Chemical shift anisotropy	2	$\{-2, -1, 1, 2\}$	1	$\{-1, 0, 1\}$
J -coupling	0	0	0	0
Dipole-dipole coupling	2	$\{-2, -1, 1, 2\}$	0	$\{-2, -1, 0, 1, 2\}$

Figure 2 Construction of CN_n^v sequences

Figure 3 Visualization of the symmetry numbers for (a) $C7_2^1$ sequences, and (b) $C14_4^5$ sequences. The left-hand helices represent the spatial rotation of the sample as a function of time. The right-hand helices depict the modulation of the rf phase as a function of time. n spatial rotations are completed in the same time as v spin rotations. The rf phase is modulated in N discrete steps, depicted by the planes in the right-hand diagrams. (Adapted from Ref.³⁹)

advance through v full rotations, in N equal steps. This idea is conveyed for the cases of $C7_2^1$ and $C14_4^5$ in Figure 3.

These symmetry properties are independent of the internal structure of the rf cycles, providing that each cycle accomplishes a final rotation through an integer multiple of 360° .

For a proof that sequences with this structure generate the Euler angle symmetry given in equation (11), see Ref.⁶⁰

For the sake of concreteness, consider a $C7_2^1$ sequence based upon the cyclic element $C = 270_0 180_{180} 90_0$, where ξ_ϕ indicates a rectangular, resonant rf pulse with flip angle ξ and

phase ϕ , and the angles are written in degrees. The full $C7_2^1$ sequence is as follows:

$$\begin{aligned} &270_0 180_{180} 90_0 270_{51.43} 180_{231.43} 90_{51.43} 270_{102.86} 180_{282.86} 90_{102.86} - \\ &270_{154.29} 180_{334.29} 90_{154.29} 270_{205.71} 180_{25.71} 90_{205.71} - \\ &270_{257.14} 180_{77.14} 90_{257.14} 270_{308.57} 180_{128.57} 90_{308.57} \end{aligned} \quad (13)$$

where the pulses are contiguous (no gaps in between). The rf field amplitude is chosen so that the entire sequence of 21 pulses fits exactly into two complete rotational periods of the sample. This requires that the spin nutation frequency in the rf field is exactly seven times the sample spinning frequency. The sequence in equation (13) is called POST- $C7$.³⁷

2.7.2 RN_n^v Sequences

A construction scheme for generating sequences with the Euler angle symmetries in equations (10) and (12) involves the following steps:

1. Select a sequence of rf pulses which rotates the nuclear spins through 180° about the x -axis. Call this element $\mathcal{R}$.
2. Change the *signs* of all rf phases within the element $\mathcal{R}$. Call this phase-inverted element $\mathcal{R}'$.
3. Select the rf amplitude so that N elements $\mathcal{R}$ occupy exactly the same time interval as n rotational periods of the sample. The number of elements N must be even in the case of RN_n^v symmetry.
4. The RN_n^v sequence consists of $N/2$ pairs of elements $\mathcal{R}_\phi \mathcal{R}_{-\phi}$, where ϕ is an overall phase shift, equal to $\phi = \pi v/N$ radians.

A simplified diagram of this procedure is shown in Figure 4 (step 2 above is omitted for simplicity). This looks similar to the set-up for a CN_n^v sequence, but with the two differences that each element provides a 180° rotation, rather than a cycle, and that the rf phase is alternated between two values, rather than being incremented.

For a proof that sequences with this structure generate the Euler angle symmetry given in equation (12), see Ref.⁶⁰

Figure 4 Construction of RN_n^v sequences

As a concrete example, suppose that one would like to build a $R18_2^9$ sequence on the composite pulse $90_0 90_{90} 90_0$, which is known to have favorable homonuclear decoupling properties.⁶¹ The first step is to establish whether this element induces a 180° rotation about the x -axis. This may be tested by rotating the three spin angular momentum operators, as follows:

$$\begin{aligned} I_x &\xrightarrow{90_0} I_x \xrightarrow{90_{90}} -I_z \xrightarrow{90_0} I_y \\ I_y &\xrightarrow{90_0} I_z \xrightarrow{90_{90}} I_x \xrightarrow{90_0} I_x \\ I_z &\xrightarrow{90_0} -I_y \xrightarrow{90_{90}} -I_y \xrightarrow{90_0} -I_z \end{aligned} \quad (14)$$

From this it may be seen that the $90_0 90_{90} 90_0$ sequence does transform I_z into $-I_z$, which is an appropriate property for a 180° rotation about the x -axis, but that it also exchanges the operators I_x and I_y , which is not appropriate. A little consideration leads to the conclusion that the $90_0 90_{90} 90_0$ sequence implements a rotation by 180° about an axis which is intermediate between the x -axis and the y -axis, i.e., phase shifted by 45° . This may also be proved by rotation operator algebra.⁶²

This defect may be remedied by phase shifting the whole sequence by -45° . This leads to the element

$$\mathcal{R} = 90_{-45} 90_{45} 90_{-45} \quad (15)$$

which now implements the correct rotation. Changing the sign of all phases leads to

$$\mathcal{R}' = 90_{45} 90_{-45} 90_{45} \quad (16)$$

The desired $R18_2^9$ sequence requires additional phase shifts of $\phi = \pm\pi \times 9/18$ radians, or $\pm 90^\circ$. The appropriate elements are therefore

$$\mathcal{R}_\phi = 90_{45} 90_{135} 90_{45} \quad (17)$$

and

$$\mathcal{R}'_{-\phi} = 90_{-45} 90_{-135} 90_{-45} \quad (18)$$

The full $R18_2^9$ sequence has the following structure:

$$R18_2^9(\text{version 1}) = \{90_{45} 90_{135} 90_{45} 90_{-45} 90_{-135} 90_{-45}\}^9 \quad (19)$$

where nine repetitions of the bracketed elements occupy exactly two rotational periods of the sample. If the phases are restricted to the interval $0-360^\circ$, we get

$$R18_2^9(\text{version 1}) = \{90_{45} 90_{135} 90_{45} 90_{315} 90_{225} 90_{315}\}^9 \quad (20)$$

If the element $\mathcal{R}$ contains no internal phase shifts, or when it only contains 180° phase shifts, then the conversion of $\mathcal{R}$ into $\mathcal{R}'$ may be ignored. For example, if a single 180_0 is used for the element $\mathcal{R}$, then the $R18_2^9$ sequence is as follows:

$$R18_2^9(\text{version 2}) = \{180_{90} 180_{270}\}^9 \quad (21)$$

where nine repetitions of the bracketed elements occupy exactly two rotational periods of the sample.

Although the construction principles of the RN_n^v sequences appear to be quite complicated, the end result is sometimes very simple.

2.8 Effective Hamiltonian

In many circumstances, the behavior of the nuclear spins under a pulse sequence may be described using the theory described in **Average Hamiltonian Theory**, Volume 2. Suppose that the pulse sequence starts at time point t^0 and lasts until time point $t^0 + \tau$. Suppose also that the period of the pulse sequence is given by $T = n\tau_r$, where n is the space winding number. The propagator for the pulse sequence between the time points t^0 and $t^0 + \tau$ is written as

$$U(t^0 + \tau, t^0) \cong U_{\text{rf}}(t^0 + \tau, t^0) \exp\{-i\overline{\mathcal{H}}(t^0)\tau\} \quad (22)$$

where U_{rf} is the propagator for the rf field alone (equation (6)), $\overline{\mathcal{H}}(t^0)$ is the *effective Hamiltonian* of the internal spin interactions, for a pulse sequence starting at point t^0 .

In a rotating sample, the effective Hamiltonian depends upon the starting time point t^0 , since the orientation of the sample constantly changes.

The effective Hamiltonian may be approximated using the Magnus expansion:

$$\overline{\mathcal{H}}(t^0) \cong \overline{\mathcal{H}}^{(1)}(t^0) + \overline{\mathcal{H}}^{(2)}(t^0) + \dots \quad (23)$$

where the first two terms are given by

$$\begin{aligned} \overline{\mathcal{H}}^{(1)}(t^0) &= T^{-1} \int_{t^0}^{t^0+T} dt \mathcal{H}_{\text{int}}(t) \\ \overline{\mathcal{H}}^{(2)}(t^0) &= (2iT)^{-1} \int_{t^0}^{t^0+T} dt_2 \int_{t^0}^{t_2} dt_1 [\mathcal{H}_{\text{int}}(t_2), \mathcal{H}_{\text{int}}(t_1)] \end{aligned} \quad (24)$$

Here $\mathcal{H}_{\text{int}}$ is the internal spin Hamiltonian, expressed in the interaction frame of the rf field. This equation employs a consistent numbering system for the Magnus expansion terms, in which the k th Magnus term is proportional to a product of k Hamiltonians. Much literature uses a more awkward numbering, in which the indices start at zero.

The term $\overline{\mathcal{H}}^{(1)}$ is called the *average Hamiltonian*. The term $\overline{\mathcal{H}}^{(2)}$ is called the *second-order correction* to the average Hamiltonian, and so on.

If the internal spin Hamiltonian is small compared to the period T of the pulse sequence, then the average Hamiltonian expansion may be terminated after the first or second term.

Note that equation (22) represents the propagator over an arbitrary interval τ , while the average Hamiltonian terms in equation (24) involve integrals over the full period of the pulse sequence. This useful approximation allows results derived for entire periodic pulse sequences to be extended, with caution, to non-integral numbers of rf cycles. We have generally found this approximation to work well for the symmetry-based sequences.

2.9 First-Order Selection Rules

The interaction frame spin Hamiltonian is a sum of many rotational components, as in equation (8). The average Hamiltonian may therefore be written

$$\overline{\mathcal{H}}^{(1)}(t^0) = \sum_{lm\lambda\mu} \overline{\mathcal{H}}_{lm\lambda\mu}^{(1)}(t^0) \quad (25)$$

where

$$\overline{\mathcal{H}}_{lm\lambda\mu}^{(1)}(t^0) = T^{-1} \int_{t^0}^{t^0+T} dt \mathcal{H}_{lm\lambda\mu}(t) \quad (26)$$

Each of these components is modulated by the spatial rotation of the sample, and the rotations of the spin polarizations induced by the rf field. If the pulse sequence is a member of the CN_n^v or RN_n^v symmetry classes, then the synchronized modulations possess the symmetry properties summarized in equations (10)–(12).

In Refs.^{45,60} it is shown that these symmetry properties lead to *selection rules* on the average Hamiltonian terms:

2.9.1 Selection Rules for CN_n^v Sequences

For CN_n^v sequences, the following selection rule applies:

$$\overline{\mathcal{H}}_{lm\lambda\mu}^{(1)} = 0 \quad \text{if } mn - \mu\nu \neq NZ \quad (27)$$

where Z is any integer, including zero.

2.9.2 Selection Rules for RN_n^v Sequences

For RN_n^v sequences, the following selection rule applies:

$$\overline{\mathcal{H}}_{lm\lambda\mu}^{(1)} = 0 \quad \text{if } mn - \mu\nu \neq \frac{N}{2} Z_\lambda \quad (28)$$

Here Z_λ is any integer with the same *parity* as the spin rank λ . If λ is even, then Z_λ takes the values $0, \pm 2, \pm 4, \dots$. If λ is odd, then Z_λ takes the values $\pm 1, \pm 3, \pm 5, \dots$.

Equations (27) and (28) are the central results of symmetry-based pulse sequence theory. These two simple equations have wide consequences.

As a first example, consider a pulse sequence with symmetry $C7_2^1$. Let us examine the fate of double-quantum dipole–dipole terms with quantum numbers $\{l, m, \lambda, \mu\} = \{2, 1, 2, 2\}$. Equation (27) states that the average Hamiltonian of this term vanishes if the quantity $mn - \mu\nu$ is not equal to an integer multiple of N . Substituting in the values $m = 1, n = 2, \mu = 2$ and $\nu = 1$ we obtain $mn - \mu\nu = (1 \times 2) - (2 \times 1) = 0$. This is an integer multiple of $N = 7$, so the term $\{l, m, \lambda, \mu\} = \{2, 1, 2, 2\}$ is *symmetry allowed*. One cannot be sure whether this term actually exists without further calculation, but at least symmetry does not exclude it. Consider now the chemical shift anisotropy term with quantum numbers $\{l, m, \lambda, \mu\} = \{2, -2, 1, 1\}$. The expression $mn - \mu\nu$ evaluates to the value $mn - \mu\nu = ((-2) \times 2) - (1 \times 1) = -5$. This is not an integer multiple of 7, so this term is *symmetry forbidden* in the first-order average Hamiltonian.

Now consider the fate of the same two terms under the symmetry $R18_1^7$, using the rule in equation (28). The homonuclear dipole–dipole terms have a spin rank $\lambda = 2$,

which is even. Equation (28) implies that a dipole–dipole term is symmetry-forbidden unless $mn - \mu\nu$ is equal to an even multiple of 9. For the term $\{l, m, \lambda, \mu\} = \{2, 1, 2, 2\}$, the expression $mn - \mu\nu$ evaluates to $(1 \times 1) - (2 \times 7) = -13$. This is not an even multiple of 9, so the term $\{2, 1, 2, 2\}$ is forbidden under the symmetry $R18_1^7$. For the chemical shift anisotropy term $\{l, m, \lambda, \mu\} = \{2, -2, 1, 1\}$, on the other hand, the expression $mn - \mu\nu$ evaluates to the value $mn - \mu\nu = ((-2) \times 1) - (1 \times 7) = -9$. This is an odd multiple of 9, and since the spin rank λ is also odd, this term is symmetry-allowed.

2.10 Space-Spin Selection Diagrams

The consequences of equations (27) and (28) are conveniently evaluated using *space-spin selection diagrams* (SSS diagrams). Two examples are given in Figure 5 and 6.

The branching lines in these diagrams show the possible values of $mn - \mu\nu$ for the particular class of spin interaction, split up into the ‘space’ part mn and the ‘spin’ part $\mu\nu$. The number of branches depends on the type of spin interaction, according to Table 2, while the spacing between the branches depends on the symmetry numbers n and v . The right-hand side of each diagram shows a barrier containing holes spaced by the symmetry number N . Those pathways that are *blocked* by the barrier represent values of $mn - \mu\nu$ which *do* satisfy the inequalities in equations (27) and (28), and represent components that are symmetry-forbidden. Those pathways that *pass* through the holes in the barrier represent values of $mn - \mu\nu$ which *do not* satisfy the inequalities in equations (27) and (28), indicating components that are symmetry-allowed. The SSS diagrams allow the consequences of the inequalities in equations (27) and (28) to be visualized clearly.

The positions of the holes depend on the symmetry class. For the CN_n^v class of symmetries, the holes in the barrier occur at levels $0, \pm N, \pm 2N, \dots$. For the RN_n^v class of symmetries, the positions of the holes depends on whether the spin rank λ is even or odd. For even ranks, the holes occur at levels $0, \pm N, \pm 2N, \dots$, as in the case of CN_n^v symmetries. For odd ranks, on the other hand, the holes occur at levels $\pm N/2, \pm 3N/2, \dots$, where $N/2$ is an integer, since N is even.

2.10.1 SSS Diagrams for $C7_2^1$ Symmetry

The behavior of the chemical shift anisotropy (CSA) terms under $C7_2^1$ symmetry is shown in Figure 5(a). There are four branches in the space part, corresponding to the $m = \{-2, -1, 1, 2\}$ components indicated in Table 2. For clarity, only the branches with $m \leq 0$ are shown: the branches with negative m are mirror images. The $m = 0$ component vanishes in the case of exact magic-angle spinning. The ‘space’ branches are spaced vertically by two units, according to the winding number $n = 2$. Each of these branches splits into three spin components, with indices $\mu = \{-1, 0, 1\}$, and spaced vertically by one unit, according to the winding number $\nu = 1$. Since the value of N is 7, the barrier on the right contains holes at levels $0, \pm 7, \pm 14, \dots$. There are no CSA pathways which pass through these holes, indicating that the average Hamiltonian contains no CSA terms. The SSS diagram shows immediately that the pulse sequence is compensated for the effects of CSA, to first order.

Figure 5 Space-spin selection diagram for C_{72} symmetry, omitting components with $m < 0$. (a) Behavior of the CSA terms. All terms are symmetry-forbidden. (b) Behavior of the homonuclear DD coupling terms. The component $\{l, m, \lambda, \mu\} = \{2, 1, 2, 2\}$ is symmetry-allowed. (c) Behavior of the isotropic chemical shift terms. The component $\{l, m, \lambda, \mu\} = \{0, 0, 1, 0\}$ is symmetry-allowed

The behavior of the dipole–dipole coupling (DD) terms under C_{72} symmetry is shown in Figure 5(b). Here too there are four branches in the space part, corresponding to the $m = \{-2, -1, 1, 2\}$ components in Table 2. Only the branches with non-negative m are shown, for the sake of clarity. Each of the space branches splits into five spin branches, with indices $\mu = \{-2, -1, 0, 1, 2\}$. As may be seen, the branch with $\{l, m, \lambda, \mu\} = \{2, 1, 2, 2\}$ passes through a hole in the barrier, indicating that this component is symmetry-allowed. The mirror-image branch with $\{l, m, \lambda, \mu\} = \{2, -1, 2, -2\}$ is also symmetry-allowed (not shown).

Since all the CSA terms are symmetry-forbidden, and the only symmetry-allowed DD terms have quantum numbers $\mu = \pm 2$, sequences with the symmetry C_{72} behave as *CSA-compensated double-quantum recoupling sequences*.

Now consider the SSS diagram for isotropic chemical shift

Figure 6 Space-spin selection diagram for R_{187} symmetry, omitting components with $m < 0$. (a) Behavior of the CSA terms. The component $\{l, m, \lambda, \mu\} = \{2, 2, 1, -1\}$ is symmetry-allowed. (b) Behavior of the homonuclear DD coupling terms. All components are symmetry-forbidden. (c) Behavior of the isotropic chemical shift terms. All components are symmetry-forbidden. Note that the positions of the holes change, depending on whether the spin rank λ is odd or even

terms, shown in Figure 5(c). Since the space and spin ranks are $l = 0$ and $\lambda = 1$, there is one space component, with $m = 0$,

and three spin components, with $\mu = \{-1, 0, 1\}$. The SSS diagram shows that the isotropic shift component $\{l, m, \lambda, \mu\} = \{0, 0, 1, 0\}$ is symmetry-allowed under $C7_2^1$ symmetry. This implies that $C7_2^1$ sequences are vulnerable to isotropic chemical shifts, unless additional precautions are taken. We return to this issue later.

2.10.2 SSS Diagrams for $R18_1^7$ Symmetry

The behavior of the CSA terms under $R18_1^7$ symmetry is shown in Figure 6(a). The left-hand side shows the two space branches with $m = 1$ and 2. The $m = 0$ component vanishes in the case of exact magic-angle spinning. The space branches are spaced vertically by 1 unit, according to the winding number $n = 1$. Each branch splits into three spin components, with indices $\mu = \{-1, 0, 1\}$, and spaced vertically by 7 units, according to the winding number $v = 7$. Since the spin rank λ of the CSA terms is equal to 1, which is an odd number, the barrier on the right contains holes at odd multiples of $N/2$, which is equal to 9 in this case. The holes in the barrier are therefore at levels $\pm 9, \pm 27, \dots$. As may be seen, the CSA term $\{l, m, \lambda, \mu\} = \{2, 2, 1, -1\}$ passes through a hole, which indicates that $R18_1^7$ symmetry is a *CSA recoupling sequence*.

The behavior of the DD terms under $R18_1^7$ symmetry is shown in Figure 6(b). The space branches with $m = 1$ and 2 split into five spin components, with indices $\mu = \{-2, -1, 0, 1, 2\}$. In the case of DD couplings, the spin rank λ is equal to 2, which is an even number. As a result, the barrier on the right contains holes at even multiples of 9, i.e., $0, \pm 18, \pm 36, \dots$. As may be seen, the barrier blocks all of the DD terms. This indicates that sequences with $R18_1^7$ symmetry are insensitive to homonuclear dipole–dipole couplings, to first order.

The behavior of the isotropic chemical shift terms under $R18_1^7$ symmetry is shown in Figure 6(c). None of the three components with $m = 0$ and $\mu = \{-1, 0, 1\}$ pass through the barrier. This indicates that sequences with $R18_1^7$ symmetry are insensitive to isotropic chemical shifts, to first order.

One may conclude that $R18_1^7$ sequences accomplish recoupling of the CSA interactions, compensated to first order for homonuclear DD couplings and isotropic chemical shifts.

2.11 Higher-Order Selection Rules

In many cases, the first-order Magnus term (the average Hamiltonian) is not a sufficiently good approximation to the effective Hamiltonian of a pulse sequence. Although the higher-order correction terms $\overline{\mathcal{H}}^{(2)}, \overline{\mathcal{H}}^{(3)}, \dots$ are more complicated than the first-order terms, they are also subject to selection rules in the case of pulse sequence symmetry.

By analogy with equation (25), the second-order term $\overline{\mathcal{H}}^{(2)}$ may be written as a superposition of many rotational components:

$$\overline{\mathcal{H}}^{(2)}(t^0) = \sum_{l_2 m_2 \lambda_2 \mu_2} \sum_{l_1 m_1 \lambda_1 \mu_1} \overline{\mathcal{H}}_{l_2 m_2 \lambda_2 \mu_2, l_1 m_1 \lambda_1 \mu_1}^{(2)}(t^0) \quad (29)$$

where each component is given by

$$\begin{aligned} & \overline{\mathcal{H}}_{l_2 m_2 \lambda_2 \mu_2, l_1 m_1 \lambda_1 \mu_1}^{(2)}(t^0) \\ &= (2iT)^{-1} \int_{t^0}^{t^0+T} dt_2 \int_{t^0}^{t_2} dt_1 [\mathcal{H}_{l_2 m_2 \lambda_2 \mu_2}(t_2), \mathcal{H}_{l_1 m_1 \lambda_1 \mu_1}(t_1)] \quad (30) \end{aligned}$$

The horrifying complexity is moderated by the following selection rules:

For CN_n^v sequences, the following selection rule applies:

$$\overline{\mathcal{H}}_{l_2 m_2 \lambda_2 \mu_2, l_1 m_1 \lambda_1 \mu_1}^{(2)} = 0 \text{ if } \begin{cases} m_2 n - \mu_2 v \neq NZ \\ \text{AND} \\ m_1 n - \mu_1 v \neq NZ \\ \text{AND} \\ (m_2 + m_1)n - (\mu_2 + \mu_1)v \neq NZ \end{cases} \quad (31)$$

where Z is any integer, including zero.

For RN_n^v sequences, the following selection rule applies:

$$\overline{\mathcal{H}}_{l_2 m_2 \lambda_2 \mu_2, l_1 m_1 \lambda_1 \mu_1}^{(2)} = 0 \text{ if } \begin{cases} m_2 n - \mu_2 v \neq \frac{N}{2} Z_{\lambda_2} \\ \text{AND} \\ m_1 n - \mu_1 v \neq \frac{N}{2} Z_{\lambda_1} \\ \text{AND} \\ (m_2 + m_1)n - (\mu_2 + \mu_1)v \neq \frac{N}{2} Z_{\lambda_2 + \lambda_1} \end{cases} \quad (32)$$

where Z_{λ_2} is an integer with the same parity as λ_2 , Z_{λ_1} is an integer with the same parity as λ_1 , and $Z_{\lambda_2 + \lambda_1}$ is an integer with the same parity as $\lambda_2 + \lambda_1$.

These selection rules are proved in Refs.^{45,60}

Although the second-order selection rules do not usually allow the elimination of all undesirable terms, they do greatly reduce the labor required to evaluate the terms. For example, in general, there are 208 components to the $\overline{\mathcal{H}}^{(2)}$ term involving commutators of dipole–dipole coupling and CSA interactions. In the presence of a $R14_2^6$ sequence, only 16 of these are symmetry-allowed.

The R-sequence selection rule equation (32) is more restrictive than that for C-sequences equation (31). As a result, R-sequences tend to have smaller numbers of higher-order terms than C-sequences, which often translates into improved performance.

The second-order selection rules allow a straightforward count of the number of symmetry-allowed terms of a particular type. Higher-order term counts may be used to get a feel for the qualitative performance of a particular symmetry, without performing detailed calculations.^{41,45} However, this rather crude criterion should not be relied on completely.

It is possible to extend these second-order selection rules to arbitrarily high orders.⁴⁵

2.12 Scaling Factors

The selection rules provide information on which terms are symmetry-forbidden. However, they provide no information on the magnitude of the symmetry-allowed terms.

In general, the form of a symmetry-allowed first-order term is as follows:

$$\overline{\mathcal{H}}_{lm\lambda\mu}^{\Lambda}(t^0) = \kappa_{lm\lambda\mu} [A_{lm}^{\Lambda}]^R \exp[-im(\alpha_{RL}^0 - \omega_r t^0)] T_{\lambda\mu}^{\Lambda} \quad (33)$$

where $[A_{lm}^{\Lambda}]^R$ is a component of the spatial tensor of interaction Λ , expressed in the rotor-fixed frame R , and $T_{\lambda\mu}^{\Lambda}$ is a component of the spin tensor of interaction Λ , expressed in the laboratory frame. The factor $\kappa_{lm\lambda\mu}$ is called the *scaling factor* of the pulse sequence, and depends upon the symmetry class, as well as the detailed structure of the basic element upon which the pulse sequence is built.

The scaling factor may be a complex number. Its magnitude is always less than one, which indicates that the suppression of unwanted terms is always accompanied by a reduction in the magnitude of the symmetry-allowed terms.

2.12.1 Scaling Factor Formulae

General formulae for the scaling factors are given in Ref.⁶⁰ In the case of CN_n^v sequences, the scaling factor for a symmetry-allowed term $\{l, m, \lambda, \mu\}$ is given by

$$\kappa_{lm\lambda\mu} = \tau^{-1} d_{m0}^l(\beta_{RL}) \int_0^\tau dt d_{\mu 0}^\lambda(-\beta_{rf}(t)) \exp[i(\mu\gamma_{rf}(t) + m\omega_r t)] \quad (34)$$

where $\tau = n\tau_r/N$ is the duration of a basic element $\mathcal{C}$, $\tau_r = |2\pi/\omega_r|$ is a rotor period, and $\beta_{rf}(t)$ and $\gamma_{rf}(t)$ are rf Euler angles [equation (6)]. The basic element $\mathcal{C}$ is assumed to extend from time $t = 0$ to $t = \tau$.

In the case of RN_n^v sequences, the scaling factor is given by

$$\kappa_{lm\lambda\mu} = \tau^{-1} d_{m0}^l(\beta_{RL}) \times \int_0^\tau dt d_{\mu 0}^\lambda(-\beta_{rf}(t)) \exp[i(\mu\gamma_{rf}(t) - \mu \frac{\pi v}{N} + m\omega_r t)] \quad (35)$$

There is an extra complex factor in this case, since the first element of a RN_n^v sequence is not the same as the basic element.

The scaling factor is calculated most readily if the basic elements of the pulse sequence do not contain any rf phase shifts, or if the phase shifts are integer multiples of 180° . This is the case of *amplitude-modulated* basic elements. For example, $\mathcal{C} = 270_0 180_{180} 90_0$ is an amplitude-modulated basic element, while $\mathcal{R} = 90_{-45} 90_{45} 90_{-45}$ is a *phase-modulated* basic element. In the case of amplitude-modulated basic elements, the rf Euler angles are given by

$$\begin{aligned} \beta_{rf}(t) &= \int_0^t dt' \omega_{\text{nut}}(t') \\ \gamma_{rf}(t) &= \pi/2 \end{aligned} \quad (36)$$

where ω_{nut} is the amplitude of the rf field, expressed as a nutation frequency (180° phase shifts may be taken into account by reversing the sign of ω_{nut}).

The calculation of the scaling factor is more difficult if the basic element is phase modulated. General formulae are given in Ref.⁶⁰ Andreas Brinkmann has written a *Mathematica*⁶³ program which provides the scaling factors of general sequences of rectangular pulses. The program is available on the web (<http://www.soton.ac.uk/~mhl>).

2.12.2 Physical Interpretation

The formulae for the scaling factor, equations (34) and (35) contain three factors. The first term, $d_{m0}^l(\beta_{RL})$ is purely spatial, and concerns the transformation of spatial rank- l tensors by the physical rotation of the sample. This term depends on the tilt of the rotation axis with respect to the magnetic field. The second term $d_{\mu 0}^\lambda(-\beta_{rf}(t))$ corresponds to the time-dependent transformation of rank- λ spin operators by the rf field. The

third term (the complex exponential factor) takes into account the physical rotation of the sample within the duration of each pulse sequence element. The formula for the R-sequence scaling factor, equation (35), contains a further phase factor, which arises because the first element of a R-sequence is phase shifted with respect to the basic element $\mathcal{R}$.

In general, it is desirable that the magnitude of $\kappa_{lm\lambda\mu}$ is as large as possible. It helps if one develops a physical feel of how $\kappa_{lm\lambda\mu}$ is generated.

In most cases, the angle β_{RL} is equal to the magic angle, so that the first term $d_{m0}^l(\beta_{RL})$ is not open to manipulation (an exception is provided by the ‘zero-field in high-field’ pulse sequences, where the choice of the spinning angle is an important element of the pulse sequence design).

In many cases, the symmetry number N is much larger than n . In this case, the duration of each element is much less than a rotor period, and it is possible to ignore the rotation of the sample during the individual rf elements, as a first approximation. This corresponds to the neglect of the $m\omega_r t$ terms in equations (34) and (35). This is called the quasi-static approximation.

In the quasi-static limit, only the rf rotations affect the accumulating time average of $T_{\lambda\mu}$ spin operators. For example, consider the problem of double-quantum recoupling. The relevant Wigner element in this case is $d_{20}^2(\beta_{rf})$, which is proportional to $\sin^2(\beta_{rf})$. This term is always positive, and is maximized at $\beta_{rf} = 90^\circ$ and $\beta_{rf} = 270^\circ$. It follows that the main contributions to the scaling factor are obtained when the Euler angle β_{rf} is close to the values 90° or 270° . At the same time, the Euler angle γ_{rf} should be kept fixed. As shown in equation (36), this may be ensured by using an amplitude-modulated basic element.

The simplest cyclic element is $\mathcal{C} = 360_0$. The rotation under this pulse takes the Euler angle β_{rf} linearly from 0 to 360° . Double-quantum excitation is accomplished near the ‘hot spots’ at $\beta_{rf} = 90^\circ$ and $\beta_{rf} = 270^\circ$. No double-quantum excitation is achieved, on the other hand, at the ‘cold spots’ $\beta_{rf} = 0$ and $\beta_{rf} = 180^\circ$. The element $\mathcal{C} = 360_0$ spends equal time near the ‘hot’ and ‘cold’ spots. Nevertheless, the appropriate Wigner element is always positive, so the scaling factor is satisfactory ($|\kappa_{2122}| = 0.157$ for the case of $C7_2^1$ symmetry).

The scaling factor may be improved by turning the rf field off near the ‘hot spots’ $\beta_{rf} = 90^\circ$ and $\beta_{rf} = 270^\circ$, allowing the double-quantum operators more time to accumulate. An example of this technique is given by the sequence

$$\mathcal{C} = 90_0 - \tau_\omega - 180_0 - \tau_\omega - 90_0 \quad (37)$$

where the ‘window’ duration τ_ω is selected so that the overall element occupies an interval $\tau = n\tau_r/N$. In the limit of infinitely strong and short pulses, the element in equation (37) provides a greatly improved scaling factor of $|\kappa_{2122}| = 0.308$ for the case of $C7_2^1$ symmetry. Although the scaling factor may be increased by introducing windows, this method has not been used very often, perhaps because the strong rf pulses make the problem of proton decoupling more acute (see below).

In practice, it is common to use elements which are locally compensated for rf inhomogeneity. This improves the robustness of the pulse sequence to rf amplitude deviations. The original version of the C7 pulse sequence used the locally-compensated element $\mathcal{C} = 360_0 360_{180}$ in a $C7_2^1$ symmetry

scheme.³⁶ In this case, each of the double-quantum ‘hot spots’ at $\beta_{\text{rf}} = 90^\circ$ and $\beta_{\text{rf}} = 270^\circ$ are traversed twice during each element. The scaling factor of $|\kappa_{2122}| = 0.155$ is almost the same as for the simple element $\mathcal{C} = 360_0$, which has $|\kappa_{2122}| = 0.157$. The values are slightly different because of the rotation of the sample during the rf element.

In the quasi-static limit, the efficiency of double-quantum recoupling is greatly reduced if the Euler angle γ_{rf} is allowed to vary. For example, the scaling factor for the phase-modulated element $\mathcal{C} = 360_0 360_{120} 360_{240}$ is given by $|\kappa_{2122}| = 0.047$ in the case of $C7_2^1$ symmetry.

If the values of N and n are comparable, the quasi-static approximation breaks down. In this case, it is necessary to think much more carefully about how the physical rotation of the sample and the spin rotations combine. Amplitude-modulated elements are no longer optimal as far as the scaling factor is concerned. For example, consider the symmetry $C7_5^1$, which provides similar selection rules to $C7_2^1$ (except that the $\{l, m, \lambda, \mu\} = \{2, \pm 1, 2, \mp 2\}$ terms are selected, rather than $\{2, \pm 1, 2, \pm 2\}$). In the case of $C7_5^1$ symmetry, the scaling factor for the allowed term $\{l, m, \lambda, \mu\} = \{2, 1, 2, -2\}$ is given by $|\kappa_{212-2}| = 0.064$ for the amplitude-modulated standard element $\mathcal{C} = 360_0 360_{180}$. This low scaling factor is due to the considerable rotation of the sample during the $\mathcal{C}$ element, leading to a strong variation of the $\omega_r t$ term in equation (34).^{39,40} The scaling factor may be greatly improved by using the phase-modulated element $\mathcal{C} = 360_0 360_{120} 360_{240}$. For the case of $C7_5^1$ symmetry, one obtains the value $|\kappa_{212-2}| = 0.144$.³⁹ The improvement in scaling factor arises because the modulations of the Euler angle γ_{rf} due to the rf phase shifts compensate the modulation of the $\omega_r t$ term, to a good approximation. Note that the phase shifts must be performed in the correct sense: The scaling factor for the element $\mathcal{C} = 360_0 360_{240} 360_{120}$, in the case of $C7_5^1$ symmetry, is only $|\kappa_{212-2}| = 0.044$.

In some cases, pulse sequences work even if the scaling factor is very small. For example, the most commonly-used version of the RFDR pulse sequence^{33,34} employs XY phase cycling and conforms to $R4_4^1$ symmetry. This symmetry is appropriate for zero-quantum DD recoupling, since it allows the homonuclear DD terms $\{l, m, \lambda, \mu\} = \{2, \pm 1, 2, 0\}$ and $\{2, \pm 2, 2, 0\}$, while suppressing other DD terms and all chemical shift terms. However, the first reports of this pulse sequence used an $\mathcal{R}$ element consisting of a strong 180° pulse followed by a ‘window’ in which the rf field is turned off. This is a puzzling choice of basic element, since the scaling factors for all symmetry-allowed DD terms vanish if the rf pulses are infinitely short. In fact, this pulse sequence reasonably well because the rf pulses always have a finite duration, so that the scaling factor is small but finite. In addition, J -couplings and higher-order effects play a role. Recent implementations of RFDR take a more sophisticated approach.^{64,65}

2.12.3 Vanishing Scaling Factors

In many cases, the scaling factors for some symmetry-allowed terms are deliberately set to zero. For example, the symmetry $C7_2^1$ allows the isotropic chemical shift term $\{l, m, \lambda, \mu\} = \{0, 0, 1, 0\}$. Pulse sequences with this symmetry are therefore vulnerable to isotropic shift variations. The basic elements $\mathcal{C} = 360_0$, $360_0 360_{180}$ and $90_0 360_{180} 270_0$ set the scaling factor κ_{0010} to zero, compensating these pulse sequences

for isotropic chemical shifts or resonance offset effects. R -symmetries such as $R14_2^6$ do not need this precaution, since all isotropic chemical shift terms are symmetry-forbidden in this case.

Another example is provided by the MELODRAMA sequence for homonuclear dipolar recoupling.⁶⁶ Some versions of this sequence are based on $C4_1^1$ symmetry. In these cases, the isotropic shift term $\{l, m, \lambda, \mu\} = \{0, 0, 1, 0\}$ is symmetry-allowed, but may be suppressed by using basic elements of the form $\mathcal{C} = (360k)_0$, where k is an integer. Other versions of the MELODRAMA sequence⁶⁶ have $R4_1^1$ symmetry, which suppresses all isotropic shift terms without extra precautions. None of these symmetries, however, remove all of the CSA terms.

The recently-described C-REDOR sequences⁶⁷ are remarkable examples of how the basic element may be designed so as to destroy undesirable symmetry-allowed terms. The main variants of C-REDOR sequences are based upon $C3_3^1$ and $C7_7^1$ symmetry. These symmetries allow CSA terms of the form $\{l, m, \lambda, \mu\} = \{2, \pm 2, 1, 0\}$ and $\{2, \pm 1, 1, 0\}$, the isotropic shift term $\{0, 0, 1, 0\}$, and also the homonuclear DD coupling terms $\{2, \pm 2, 2, 0\}$ and $\{2, \pm 1, 2, 0\}$. However, by choosing a basic element $\mathcal{C} = 90_0 360_{180} 270_0$, the scaling factors of all terms vanish, except for those belonging to the CSA terms $\{2, \pm 1, 1, 0\}$. These sequences may therefore be used to selectively recouple CSA terms while suppressing the isotropic chemical shifts and homonuclear DD couplings. C-REDOR has been applied to the selective recoupling of heteronuclear DD interactions,⁶⁷ which behave in the same way as the CSA terms, if the rf field is resonant with only one spin species (see below).

The vanishing scaling factors of certain terms under specific pulse sequences is probably due to additional symmetries. This is a promising area for further theory.

2.13 Orientation Dependence
